An apparently intact intellectual level frequently obscures other cognitive challenges and thus is not a reliable indicator of recovery following pediatric TBI. Nonetheless, studies using IQ as an outcome variable can yield some general findings as to overall patterns of recovery. A recent investigation by Crowe and colleagues⁵⁷ suggested that children sustaining a TBI in middle childhood actually had worse outcomes than did children sustaining injuries in early or late childhood. The investigators suggested that this result might reflect a window of vulnerability in brain maturation occurring during middle childhood. In another study, this group demonstrated significant decreases in intellectual functioning, assessed between the ages of 4 and 6 years, in children who sustained a severe TBI before the age of 3 years.⁵⁸ Ewing-Cobbs and collaborators⁵⁹ reported a similar finding when they observed continued deficits in intellectual functioning in children who had sustained a severe TBI before the age of 6 years and were followed for 5 years after injury. Conversely, Anderson and colleagues⁶⁰ showed that as a group, survivors of childhood TBI did not exhibit significant decreases in terms of intellectual abilities 10 years after injury, although these investigators cautioned that survivors of severe TBI had a less benign course. A recent study of adult survivors of pediatric TBI indicated relatively intact intellectual functioning, although significant decreases in IQ and quality of life were noted in those individuals who had sustained severe injuries.⁶¹ Head-injured children who have IQ scores within the normal range can, nonetheless, exhibit a variety of problems, some of them long term. For example, a study of children age 9 to 18 years injured approximately 4 years earlier demonstrated that IQ was not correlated with problem-solving skills within a social context.^{62,63} Another study noted that children with normal IQ scores exhibited subtle language differences in the classroom.⁶⁴

57.5.2 Motor and Visual-Motor Skills

Motor problems are perhaps the most easily recognized sequelae of head injury and are observed to some degree in nearly all children after moderate to severe head injury. Early work by Levin and Eisenberg identified deficits on tests of stereognosis, finger localization, and graphesthesia in approximately 25% of children with severe head injuries.⁶⁵ Others have shown that children with severe injuries are most affected when balance and speed of performance are essential to successful task completion. In a recent investigation, Sutton and colleagues⁶⁶ found that children with TBI exhibited significant decrements on a measure of visual-motor integration skills when compared with a population of children who had attention-deficit/hyperactivity disorder (ADHD). A series of investigations by Caeyenberghs and collaborators indicated not only that children with TBI exhibit a variety of motor impairments, including difficulties with manual dexterity, hand-eye coordination, and postural control, but also that many of these motor anomalies are associated with changes to white matter tracts (see Caeyenberghs et al⁶⁷⁻⁷⁰). Residual motor deficits have long-lasting functional significance in recreational activities and, later, in the workplace. A 1996 study⁷¹ described strength, agility, and coordination problems that limited children's participation in sports. Emanuelson et al⁷² described fine-motor deficits severe enough to affect

vocational outcome for as long as 7 years after severe injury during childhood or adolescence.

57.5.3 Speech and Language

Severe oral-motor disturbances, including dysarthria and dysphagia, are rare throughout the entire spectrum of pediatric TBI; however, Morgan et al indicated that these conditions are significantly more common following severe injury (upward of 75% of survivors of severe pediatric TBI) and can have profound effects upon recovery.⁷³ Spontaneous mutism and classic aphasic syndromes, including dyscalculia, dysgraphia, and expressive aphasia, are commonly observed in the acute recovery phase, although these effects are usually not long term.⁷⁴ On the other hand, researchers have shown that communication problems are often present in children who do not demonstrate aphasia and that these deficits can persist, particularly after severe head injury.⁷⁵ These linguistic impairments can include increased latency in naming objects, reduced verbal fluency, problems in writing to dictation, difficulty copying sentences, problems with written expression, particularly production speed and complexity, and slower-than-normal spontaneous speech.⁷⁴

Expressive and Receptive Language

Residual communication deficits after childhood head injury are common^{10,14,62} and can occur after head injury of any degree of severity. Research suggests that deficits noted after severe injury persist for years and substantially impact quality of life.^{10,15,16} A controlled study of youngsters aged 3 through 7 years at the time of head injury identified no differences between groups with respect to intellectual ability, adaptive competence, or behavior when the children were compared with healthy, appropriately matched peers. However, small but significant differences persisted for 2½ years after injury on a verbal test that required the comprehension and integration of complex material and on a verbal fluency task.¹⁷ Another longitudinal study of children injured between the ages of 5 and 15 years found that severe head injury adversely affected verbal fluency for as long as 5 years after injury. In comparison with children who had milder injury, their rate of language development was slower and did not reach the level predicted for their age. In addition, children injured at a younger age had a slower rate of recovery than did children who were injured when they were older.¹⁴ Hanten et al⁷⁶ found continued deficits in expressive language abilities during a 2-year follow-up of children with moderate to severe TBIs when they were compared with children who had sustained only mild injuries. However, participants within all three groups exhibited a similar trajectory of improvement. Results also indicated that younger children demonstrated more deficits regardless of injury severity and that children from higher socioeconomic levels demonstrated a faster rate of recovery of skills.

Long-term difficulties (i.e., 1 year or more after injury) have been observed in more foundational language tasks, such as confrontation naming and phonologic word retrieval.⁷⁷ Language disruption following pediatric TBI has also been demonstrated with functional brain imaging techniques. A 2007 investigation showed changes in activation patterns within

language-related cortical areas in a group of children who had sustained a closed head injury when they were compared with normal controls.¹⁸ Interestingly, these alterations were correlated with performance on neuropsychological measures of linguistic abilities, and changes occurred even though many of the participants with TBI exhibited relatively few structural lesions on conventional MR imaging.

Pragmatic Language

Impairment of pragmatic language may be observed in children after head injury.¹⁵ Pragmatic language, or discourse, is defined as language, either narrative or conversational, that is used to communicate with others and to meet the speaker's needs. Literature suggests the sparing of language capacity in young children who have undergone hemispherectomy, and the effect of head injury on developing linguistic skills is of particular interest.³⁵ Dennis and Barnes found that after severe head injury, children were most deficient in tasks that required understanding inference and intentions—abilities that have a significant impact on classroom performance.²⁰ Chapman and collaborators²¹ found deficits in discourse skills in children who had sustained either a mild or severe TBI when they were compared with uninjured peers. The investigators also demonstrated that working memory skills were correlated with discourse performance. Deficits in pragmatic language are also associated with social outcome, and these issues can become more salient as children mature.⁶³

57.5.4 Memory and Learning

Memory impairments are perhaps the most commonly discussed sequelae of brain injury in children. Deficits in *explicit memory*, which is the conscious recollection of previous experience (i.e., free recall, cued recall, and recognition), that occur after head injury in school-aged children are well characterized elsewhere.^{22,23,26,27,75,78} Anderson et al⁴⁸ are one of the few research groups to study the recovery of memory in young children, probably because the memory tests available for this age group are limited. Their research demonstrated that in the acute recovery period, younger children across the spectrum of injury severity exhibited memory problems. Although a more robust relationship between memory impairment and injury severity developed over time, there was also evidence that memory and learning actually *deteriorated* or failed to progress in some youngsters with moderate to severe injury. In a subsequent investigation, Anderson and Cattoppa⁷⁹ demonstrated that children with severe TBI injured during middle childhood exhibited long-term deficits in complex verbal memory abilities assessed at 5 years after injury. These authors also observed persistent deficits in verbal and visual memory skills in children sustaining a severe TBI and indicated that these deficits were associated with academic performance.⁸⁰ In a unique investigation, Salorio and colleagues⁸¹ reported that performance on a verbal learning task at 1 year after injury was strongly related to the volume of brain lesions outside the frontotemporal areas. The authors speculated that these results were indicative of diffuse axonal injuries that disrupted connections important for memory encoding, consolidation, and retrieval processes.

It is also important to consider how head injury affects prospective memory. In contrast to the recall of events from the past, *prospective memory* is the recall of intentions to be performed at a future time.⁸² Prospective memory is described as event-based (i.e., there is an external cue such as a timer), time-based (i.e., a scheduled appointment), or activity-based (i.e., a specific action is to be performed either before or after another event). Activity-based prospective memory is the only task that does not require the interruption of ongoing activities. As these examples illustrate, prospective memory supports adaptive behavior, such as completing errands, keeping appointments, or following instructions at a future time. Research shows that prospective memory develops early in life, being reported in children as young as 2 years. In one of the first studies in this area, researchers evaluated prospective memory in a sample of children 5 years after severe TBI.⁸² Performing a challenging mental task for less than 15 minutes resulted in prospective memory failures in more than 90% of the severely head-injured group. Furthermore, prospective memory deficiency remained even after a reminder had been provided. Difficulties in prospective memory were related to everyday problems, including maintaining the intention to complete a task in the face of ongoing attentional and task demands. Simple reminders or cues did not improve performance, suggesting that different strategies are needed to improve functioning. In a series of more recent investigations, McCauley and collaborators demonstrated that the prospective memory skills of children with TBI can be improved in tasks with a high incentive value (e.g., a large versus a small monetary reward).^{83–85} However, these investigators cautioned that although the group with severe TBI exhibited some improvements, their performance within the high-motivation condition continued to fall short of that of the control group under the low-motivation condition, suggesting persistent and significant deficits in prospective memory skills in children sustaining a severe TBI.⁸³

Recent investigations have also addressed *implicit memory* after childhood brain injury. Implicit memory occurs and can be demonstrated without deliberate awareness. Two examples include priming (i.e., the facilitation of learning that occurs by prior exposure to a stimulus) and procedural learning (e.g., skiing or maze learning). For a review of this literature, see Schacter et al.²⁰ Shum et al.⁸⁶ used a visual priming task to study implicit memory in a group of children aged 8 through 14 years with severe head injury and in healthy controls. The children were shown picture fragments and later the complete pictures intermixed with a group of novel pictures. Both groups showed an equal priming effect despite group differences on an explicit memory task. Noting the possibility of dissociation between various types of implicit memory, the investigators compared a group of moderately to severely head-injured children with a group of healthy controls on a measure of procedural memory.⁸⁷ No significant differences between groups were identified on either a rotary pursuit task or a mirror-reading task. However, in a recent investigation, Lah and colleagues⁸⁸ found that children sustaining a TBI before the age of 6 years exhibited deficits on measures of implicit as well as explicit memory when compared with either children injured later in childhood or uninjured controls. Given these mixed findings, future studies that evaluate different types of implicit memory skills following pediatric TBI occurring at various ages appear warranted.

57.5.5 Attention and Executive Function

Because trauma commonly affects the macrostructure and microstructure of frontal brain regions either directly or indirectly,⁸⁹ a marked trend in recent outcome research is to delineate more clearly the deficits associated with injury to these frontal brain regions. Frontal lobe injury, in particular, accounts for deficits in higher-order attentional skills, problem solving, planning, judgment, and information processing, as well as the personality changes frequently observed in children with TBI. These higher-level abilities, grouped under the rubric of executive function, serve to manage and coordinate both cognition and behavior.⁹⁰ The long-term impact of the disruption of executive skills that occurs during childhood remains poorly understood.⁹¹ However, the assessment of executive abilities in the near term after traumatic head injury provides the critical information necessary to plan subsequent interventions.

In a review of the extant literature on attention deficits following pediatric TBI, Ginstfeldt and Emanuelson⁹² suggested that divided attention and sustained attention appear most vulnerable to closed head injury, whereas simple attention span is more robust to disruption. These authors also indicate that most of the significant gains in attention skills can be expected within the first year after injury, with many individuals experiencing persistent deficits into adulthood. Interestingly, a study by Thaler and colleagues⁹³ observed differences between component aspects of attention skills in children following TBI and children diagnosed with ADHD. These authors indicated that children sustaining a TBI exhibited difficulties in the domains of focus and encoding, whereas children with primary ADHD exhibited difficulties in the domains of sustaining and encoding. These and other findings (see Anderson et al.,⁹⁴ Kramer et al.,⁹⁵ Levin et al.,⁹⁶ and Sinopoli et al.⁹⁷) suggest that children with attention problems secondary to TBI exhibit a neurocognitive and symptom profile that differentiates them from children with a diagnosis of idiopathic ADHD. In a 2011 investigation,⁹⁸ Catroppa and colleagues indicated that at 10 years after injury, attentional skills were not normally developed in a group of children who had sustained severe head injuries before the age of 6 years.⁹⁹ This investigation indicated that attention abilities developing early and more complex attentional skills developing later appeared most vulnerable to an injury sustained in the preschool period.

Working memory is an aspect of memory subsumed by the frontal brain regions that has recently received scrutiny in the pediatric outcome literature. Working memory is of limited capacity and is age-dependent. Through processes of storing, monitoring, and manipulating information, working memory mediates the development of many complex cognitive processes and academic skills.¹⁰⁰ Noting the vulnerability of the prefrontal regions to closed head injury and the structure of the frontal lobes, Levin et al.⁸⁹ investigated the impact of head injury on working memory in children. The investigators used a working memory test that allowed adjustment of the memory load (the n-back task) and evaluated children across the spectrum of injury severity at 3, 6, 12, and 24 months after injury. Children who sustained severe injury showed a decline in working memory between 1 and 2 years after injury, whereas less severely injured patients continued to demonstrate age-

appropriate gains. In a recent investigation, Gorman and colleagues¹⁰¹ demonstrated deficits in visual and verbal working memory skills following pediatric TBI. This study also indicated that these difficulties were not secondary to other executive dysfunctions (e.g., problems with inhibitory control).¹⁰²

Research is beginning to elaborate on the impact of metacognition on the executive abilities of children who have experienced severe head injury. According to information-processing theory,¹⁰³ metacognition refers to self-regulatory activities that monitor performance effectiveness and adjust strategies to enhance performance. With respect to memory ability, metacognitive management (i.e., employment of effective memory-enhancing strategies) usually begins to develop at the age of 6 years. Hanten et al¹⁰⁴ investigated metacognitive judgment in nine 7- to 13-year-old children, seven of whom had documented frontal injury. In this controlled study, children were asked to make two predictions: (1) how easy it would be to memorize each word in a 15-word list and (2) how many words from the list would be recalled after a 2-hour delay. Interestingly, the head-injured group showed no significant difference in learning when compared with the control group. In contrast, the head-injured group evidenced significant impairment in both predictions of task ease and performance level during the recall task. A study by Crowther et al¹⁰⁵ also demonstrated that children with moderate or severe TBI exhibited changes in their learning strategies and meta-memory judgments over a 2-year follow-up interval when compared with children who had sustained only a mild injury. Interestingly, although children with moderate or severe TBI demonstrated a faster rate of improvement in their performance during the first 12 months after injury, their scores peaked at this time point and then gradually began to diverge from those of children in the mild injury group between 12 and 24 months after injury.

A recent investigation by Wilson et al¹⁰⁶ indicated that adolescents who had sustained a TBI reported significantly fewer metacognitive, but not behavioral executive, deficits than their parents did. The number of their reports was also decreased when they were evaluated against the self-reports of uninjured age-matched peers. The authors suggest these findings are indicative of deficits in self-awareness and understanding of limitations within the TBI group. Taken together, these findings suggest that children who sustain a significant head injury can exhibit a general metacognitive deficit when asked to assess their own level of skill, the difficulty of a task, or the cognitive demands necessary for successful task completion. Finally, the pattern of results observed in the study of Crowther et al¹⁰⁷ suggests that children with moderate or severe injuries may make significant gains in meta-memory judgments in the first year after injury but may evidence a lag in age-appropriate maturational processes after this initial burst of recovery.

The impact of executive deficits is not limited to performance on working memory or meta-memory tasks. Aspects of social problem solving and behavioral regulation have been shown to be associated with the severity of injury to the frontal brain regions.^{108,109} Janusz and colleagues⁶⁴ investigated social problem-solving skills with a developmental model of social reasoning. The relationship between developmental level and social outcome was compared in three injury groups: severe head injury, mild head injury, and orthopedic injury. Findings indicated that children with severe head injury defined social dilemmas

and generated alternative solutions at the same developmental level as the control children. However, the *quality* of their solutions was poorer—that is, they described lower-level strategies as the “best” solution and used lower-level reasoning to evaluate the effectiveness of their strategies. In a similar investigation, Ganesalingam et al¹¹⁰ demonstrated that the social problem-solving difficulties of children with TBI were associated with deficits in self-regulation as assessed by performance measures and parent and teacher reports. A study by Levin et al¹¹¹ demonstrated that measures of cognitive control (e.g., working memory and inhibition) were positively related to social outcomes at 12 months after injury as assessed by the VABS. This study also showed that the relationship was stronger in children from lower socioeconomic backgrounds, suggesting an interaction between socioeconomic status and postinjury social outcomes.

Problem Behaviors

Behavioral changes within the 2-year recovery period are now well characterized in the outcome literature. Research in the 1980s and early 1990s established that premorbid psychiatric disturbances and severity of trauma were the best predictors of postinjury behavior problems. A significant number of children developed new behavior problems after head injury. Cole and colleagues¹¹² demonstrated that increases in aggressive behavior are very common following pediatric TBI. Furthermore, children with preexisting attention problems and anxiety as well as children with higher levels of disability were at the greatest risk for developing symptoms of aggression at 1 year after injury. A follow-up investigation by Gerring et al⁴² demonstrated that the prevalence of preinjury conduct disorder in children sustaining a TBI was higher than that in an age-matched and demographically matched population, but the TBI group also displayed a significantly higher rate of conduct disorder and disruptive behavior symptoms at 1 year after injury in comparison with uninjured, matched controls. A recent investigation by Max et al¹¹³ indicated that approximately 50% of children sustaining a moderate to severe head injury developed symptoms of a novel psychiatric diagnosis at 3 months after injury. This was compared with 13% of orthopedically injured controls and was not accounted for by preinjury functioning, family psychiatric history, or environmental factors.

Noting that behavior problems often persist well past the 2-year recovery period, recent work has attempted to characterize the behavior problems in children with head injury that fail to resolve^{63,64,114,115} or even worsen over time.^{108,109} A controlled study by Taylor et al⁶² investigated behavior over a 4-year period by comparing children who had moderate or severe head injury with an orthopedic control group. The level of behavior problems did not change as a function of time (i.e., short-term vs. long-term follow-up), suggesting the stability of these sequelae. Children in both the severe- and the moderate-injury groups showed poorer competence (i.e., school performance, activities, and social function) and everyday communication skills in comparison with the children who had orthopedic injuries. As the authors noted, a portion of children with moderate and severe injuries exhibited behavior problems for as long as 4 years after injury. These were exacerbated by family

environments characterized by limited resources and poor overall functioning.

Academic Skills

Numerous studies have documented changes in academic functioning following pediatric TBI. Taylor and colleagues¹¹⁶ examined school readiness skills in a group of children who had sustained a TBI before 6 years of age. Results indicated that children within the severe TBI group exhibited decrements in school readiness skills at a 6-month follow-up. Performance was predicted by injury-related variables and to some degree was moderated by environmental factors. A study by Ewing-Cobbs et al¹¹⁷ found that children who had sustained a TBI showed significant improvement in terms of academic skills performance over a 2-year follow-up interval; however, children in the severe TBI group continued to demonstrate marked deficits across academic domains. Children who were younger at the time of injury exhibited a decelerating rate of improvement in academic skills when compared with children who sustained similar injuries at an older age. In another investigation, Ewing-Cobbs et al¹¹⁸ demonstrated that children who had sustained a TBI before 6 years of age continued to exhibit academic deficits at a mean of 5 years after injury. This study also found that 50% of children in the TBI group had either failed an academic grade or required a primary placement in a special education classroom. Hanten and colleagues⁷⁶ demonstrated impairments in reading comprehension scores in children with severe TBI when compared with children sustaining either mild or moderate head injuries. Interestingly, this study indicated that lower-level reading skills, including reading rate, accuracy, and decoding skills, did not differ between children with mild, moderate, or severe TBI. Similar to the Ewing-Cobbs investigations, this study found that children injured at an earlier age experienced more difficulties in reading comprehension skills regardless of their age at the time of assessment.

Written language skills also appear to be affected by the severity of injury and age at injury. In one study of children and adolescents, written language was more impaired in the children in the sample who were between the ages of 5 to 10 years, an effect not seen in naming, expressive, and receptive language skills.¹¹⁹ Because written language skills show the most rapid development between the ages of 6 and 8, this finding lends support to the idea that developing abilities are those most vulnerable to disruption by brain injury.

57.6 Treatment and Rehabilitation

Although the acute outcome of children with head injury is necessarily of primary interest to the readers of this text, the treatment of the longer-term consequences of head injury is also relevant. Previously, we have discussed chronic difficulties with attention, organization, information processing, working memory, and problem solving that directly influence

learning. These cognitive deficits often lead to academic delays, significant behavioral disturbances, difficulties with socialization, family discord, and long-term problems with vocational attainment, all of which are appropriate targets for intervention.

57.6.1 Pharmacologic Treatment of Frontal Lobe Symptoms

Despite the vital influence that attention, monitoring, and organization have on learning, there continues to be a dearth of information regarding effective pharmacologic interventions directed at the specific cortical systems that subsume those cognitive functions and are perturbed by closed head injuries.¹²⁰ Amantadine hydrochloride (AMH), a dopamine agonist, has a long history of use in the pediatric population, although few empiric investigations have been conducted of its effectiveness in pediatric patients with TBI. Beers and colleagues completed a small pilot investigation examining the ability of AMH to improve outcome in pediatric patients following TBI.¹²¹ Children with a history of head injury who were experiencing clinically significant symptoms of executive dysfunction were randomized to treatment or to a usual and customary care condition. Neuropsychological assessment was completed at baseline and immediately after the 12-week treatment phase. Among the children who received AMH, the side effects were generally mild and remitted after the first week. Results indicated that children in the medication group evidenced statistically significant improvement in comparison with children in the usual care group in parent-reported measures of executive skills and promising trends in laboratory measures of executive abilities. These results are tempered by the lack of a placebo-controlled design. Small sample size also limits the ability to ascertain the important effects of age, gender, and injury level on response to AMH. A more recent pilot study by Scott et al¹²² indicated that ziprasidone may reduce symptoms of agitation and aggression in the acute stage of recovery after pediatric TBI. For a thorough review of the medication management options for pediatric patients with TBI, please see Pangilinan et al.¹²³

57.6.2 Cognitive Rehabilitation

As discussed throughout this chapter, impairments of cognition and behavior after traumatic head injury often persist long after neurologic symptoms have remitted.¹²⁴ Thus, although children with severe head injury usually receive inpatient rehabilitation services, longer-term services at home and sometimes at school are often needed. This rehabilitation is optimally completed by an interdisciplinary team of physical therapists, occupational therapists, speech pathologists, psychologists, educators, and parents, with the specific goal of the child's successful reintegration at home and in school.¹²⁵ Children with brain injury frequently benefit from secondary interventions that they complete with parents and the schools. Unfortunately, few empiric studies have assessed the efficacy of any of these interventions.

Rehabilitation Programs

Understanding a child's pattern of cognitive and behavioral strengths and weaknesses is a critical component of successful cognitive rehabilitation programs. With this information in hand, rehabilitation specialists use a variety of techniques, with the common goal of establishing new patterns of cognitive activity by reinforcing or re-establishing previous patterns of behavior, using compensatory cognitive mechanisms to replace impaired abilities, providing external compensatory mechanisms, such as personal orthoses or increased structure and support, and providing therapeutic interventions that enable individuals to come to terms with their limitations, thereby improving their overall quality of life.¹²⁴ For a review of the approaches to cognitive rehabilitation and behavioral management used in pediatric TBI interventions, see Catroppa and Anderson,¹²⁶ Semrud-Clikeman,¹²⁷ and Ylvisaker et al.^{128,129}

Acknowledging the lack of efficacy studies in the pediatric literature and the ever-present problem of maintenance and generalization with extant techniques, Ylvisaker and Feeney¹²⁵ and Park and Ingles¹³⁰ propose what they term "context-sensitive" rehabilitation. One goal for such intervention techniques is to prevent predicted behavioral deterioration and social skills deficits from occurring in the longer term after brain injury. This approach recognizes that the effects of pediatric TBI on foundational skills like attention and executive functioning will in turn have profound effects on other cognitive domains as well as on the implementation and eventual success of rehabilitation programs. Intervention techniques, chosen on an individualized basis, might include those that are impairment-oriented (e.g., empirically validated retraining exercises), activity-oriented (e.g., *compensatory* strategies that allow the individual to participate in an activity with a support that reduces the disability without changing the underlying cognitive impairment), and participation-oriented (e.g., environmental modifications encompassing both the concrete environment and the psychosocial environment).

Efficacy studies of these context-sensitive rehabilitation procedures are limited. Two studies are of particular interest because they involved children. Feeney and Ylvisaker¹³¹ evaluated a context-sensitive support-oriented behavioral and cognitive intervention to improve the behavioral self-regulation of two children who had experienced brain injury 1 to 2 years earlier. Both children had sustained severe frontal injuries, and upon return to the classroom they exhibited serious cognitive and behavioral problems. The rehabilitation intervention, which included behavioral supports, cognitive supports, and specific routines to support deficient executive skills, was highly individualized and completed in the classroom. After the initial intervention had been completed, a maintenance program was continued at school and completed at home. Both children achieved acceptable levels of behavioral control within approximately 1 month. Training was provided to ensure that environmental modification and successful instructional techniques continued over the next school year. These highly individualized and labor-intensive procedures resulted in positive results

not only at 1-year follow-up but also for as long as 9 years after the initial injury.

Other, less labor-intensive cognitive interventions have also demonstrated some effectiveness. In a small pilot study of a Web-based cognitive rehabilitation intervention, Wade and collaborators¹³² found evidence of improvements in self-reported executive abilities in a group of adolescents after TBI when they were compared with an education-only group that had similar characteristics.

Family Interventions

In accordance with the growing body of research noting that a child's recovery from head injury is correlated with family function, many hospitals and rehabilitation programs now offer support services for parents. These groups provide a venue in which parents can express feelings and resolve emotional problems within the family. Evidence suggests that parenting interventions can be very beneficial in improving family functioning and in promoting functional recovery in children following a TBI.¹³³ In a recent case study, Cohen and colleagues¹³⁴ demonstrated the effectiveness of parent-child interaction therapy in reducing externalizing behavior problems and improving parent adjustment in an 11-year-old boy who had sustained a TBI. Interestingly, this case study successfully employed a therapeutic approach typically used in much younger children, suggesting that a flexible approach can be employed in the design of intervention programs for children and families coping with a TBI.

Some pilot programs have also begun to use Web-based curricula to facilitate the delivery of family and cognitive interventions. Although the evidence base is small, these pilot programs have shown promise for improving parent coping and family functioning in general, and in effecting modest gains in cognitive skills in children with a TBI.¹³⁵⁻¹³⁷ For a review and a discussion of guidelines for family interventions following pediatric TBI, see Cole et al.¹³⁸

School-Based Interventions

Almost all children who survive a TBI return to the classroom.¹³⁹ Because children experiencing the longer-term sequelae are now understood to have an educational disability, modifications and specialized instructional techniques have come under increased scrutiny.¹⁴⁰ Interventions provided in the school setting can include assistive technologies,¹⁴¹ curricular and classroom modifications, and specialized "pull-out" services (i.e., individual physical, occupational, and speech and language therapies). The provision of these educational modifications and services is based on an individualized educational plan that identifies appropriate learning criteria, specific instructional procedures and modifications, and the learning environment that best meets the needs of the individual child. The most successful individualized educational plans provide for a comprehensive assessment of the

student's strengths and weaknesses as well as for staff education regarding TBI.¹⁴² Interestingly, educators are beginning to recognize the degree of developmental disruption caused by dysexecutive symptoms and emphasize the remediation of executive skills with programs that address learning strategies¹⁴³ and social skills.¹⁴⁴ (See Szekeres and Meserve¹⁴⁰ for an extended discussion of these techniques.)

57.7 Summary and Conclusion

Head injury is the most frequent cause of acquired brain injury in children, with an incidence of approximately 100 hospitalizations per 100,000 persons. In contrast to the excellent recovery reported in most children sustaining mild head injury, those with moderate to severe head injury show adverse effects in the development in cognitive, language, motor, adaptive, and psychosocial domains. Apart from the severity of injury, age less than 5 years and an adverse family environment are related to persistent sequelae of head injury. Within the cognitive domain, intellectual ability as measured by conventional standardized tests frequently shows a trend toward recovery after severe head injury and eventually approximates the normal range in most children. However, deficits in explicit memory and learning, attention, and executive functions, such as planning and self-regulation, frequently persist despite the apparent recovery of intellectual ability. Although language deficits can be pervasive during the initial phases of recovery from severe head injury, pragmatic skills, including the organization and processing of narrative discourse, are among the most persistent communication deficits. Residual problems with learning and explicit memory, which frequently persist despite initial improvement, contribute to reduced academic achievement in children following moderate to severe head injury. In contrast, retention of overlearned skills and implicit learning are relatively preserved. Executive functions as measured by laboratory tasks, such as planning, metacognitive measures, such as estimating one's learning and retention, and self-regulation of behavior in daily activities as rated by parents and teachers are frequently impaired for long intervals after moderate to severe head injury. Information processing speed tends to slow after moderate to severe head injury and detracts from performance in various domains. Similarly, slowing of motor speed is a frequent sequela of moderate to severe injury. Importantly, more recent studies have reported unexpected late declines in cognitive skills, such as working memory and attention. Adaptive functioning in relation to age expectation can also decline following severe head injury. The integration of cognitive skills with social processing, as in social problem-solving tasks, appears to be a useful approach to elucidating the sequelae of severe head injury and holds potential for the development of effective behavior intervention. To date, researchers have proposed such interventions to mitigate disability after head injury in children, but evidence for their efficacy is generally limited to case reports and group studies that lack randomized, placebo-controlled designs. However, initial studies of both pharmacologic and cognitive interventions have reported positive results that serve to encourage clinical trials.

Pearls

- The assessment of outcome depends on a careful consideration of preinjury risk factors. In children, brain injury occurs to a developing brain. Recovery is correlated with preinjury factors that continue to influence development after brain injury, as well as with injury- and family-related factors that can affect recovery in various areas of functioning. Children may recover to their preinjury level but fail to maintain the same rate of development that they had before the injury occurred.
- The emotional, behavioral, and cognitive deficits associated with pediatric brain injury often do not stabilize after the usual 2-year recovery period. It is not unusual to identify new deficits as a child matures. This may surprise parents, who expect further recovery as opposed to increased problems as the child matures.
- The functional significance of injury to the frontal brain regions has received increased scrutiny over the past decade. The impact that impairment of higher-order attentional skills, problem solving, planning, and judgment (i.e., the executive deficits) has on social, educational, and personality function is increasingly appreciated.
- A comprehensive neuropsychological evaluation completed at 1 year after injury can help track recovery. In addition, because of the changing pattern of deficits that can occur through childhood, follow-up evaluations at regular intervals serve to refine treatment planning and educational interventions.
- Although the new cognitive rehabilitation programs and educational interventions developed to address deficient executive abilities appear promising, efficacy studies are lacking.

58 Cranioplasty

James Tait Goodrich

The use of cranioplasties in the pediatric population has undergone a number of significant changes during the last 25 years. A newer appreciation has developed of what materials can be implanted in a child and what materials cannot.

To put the subject in perspective, this chapter begins with a historical introduction that reviews the techniques introduced by surgeons over the last several hundred years. The types of cranioplasties currently in use are reviewed specifically as they apply to children and adolescents. The fact that childhood is a phase of continual growth, and infancy of rapid growth, means that a great deal of thought has to go into the repair of cranial defects in this unique surgical population. Cranioplasty entails distinctive considerations in each pre-adult phase of life—infancy, childhood, and adolescence—and these, too, are discussed. The various cranioplasty repair materials are reviewed, along with their unique ability or inability to repair a defect well. Complex scalp injuries are often associated with cranioplasty; therefore, techniques for their repair are also reviewed.

58.1 Early History of Cranioplasty

In reviewing the history of repairing holes in the head, one is continually amazed by what our surgical brethren have used as materials for cranioplasties. A phenomenal variety of materials have been used over the years to repair holes in the head. Although not a surgeon, Hippocrates provided evidence of considerable surgical expertise in his writings on skull injuries. In dealing with comminuted compound fractures of the skull, Hippocrates advocated the removal of free skull fragments. In place of the bone, lint dressing soaked with wine was placed—an interesting and very early technique for achieving wound asepsis. The wound edges were pulled together and secured with adhesive lint segments.^{1–3}

The first printed work to deal with injuries to the head, *Tractatus de Fractura Calvae sive Cranei* (“Treatise on Fractures of the Calvaria or Cranium”), was written by Berengario da Carpi (ca. 1460–1530) and published in 1518.⁴ Berengario offered several suggestions for dealing with fractured skulls, some of which would not be accepted today: “When large parts of the skull are removed, the wound should be sprinkled with shredded dry gourd (*frustulum cucurbitae siccae*), which promotes healing. Smaller defects are covered with ‘flesh’ [*carne*]—this is done to allow free drainage of the *sanies*; after that time, unguents may be applied.”⁴ In the same period (1517), a European surgeon, Hans von Gersdorff (1455–1529), described a cranioplasty made of a mixture of wine and wood oil and packed with wood wool; this was compressed until it became hard.⁵ However, Gersdorff appropriately noted that it should not be pressed hard against the dura because to do so would be “deadly” (► Fig. 58.1).

In South America, in what is now Peru, the Chimu and then later the Inca were skilled surgeons when it came to the management of head injuries. Recently excavated human skulls reveal some of the earliest uses of metal implants to repair skull defects. In museum collections are a number of skulls that were

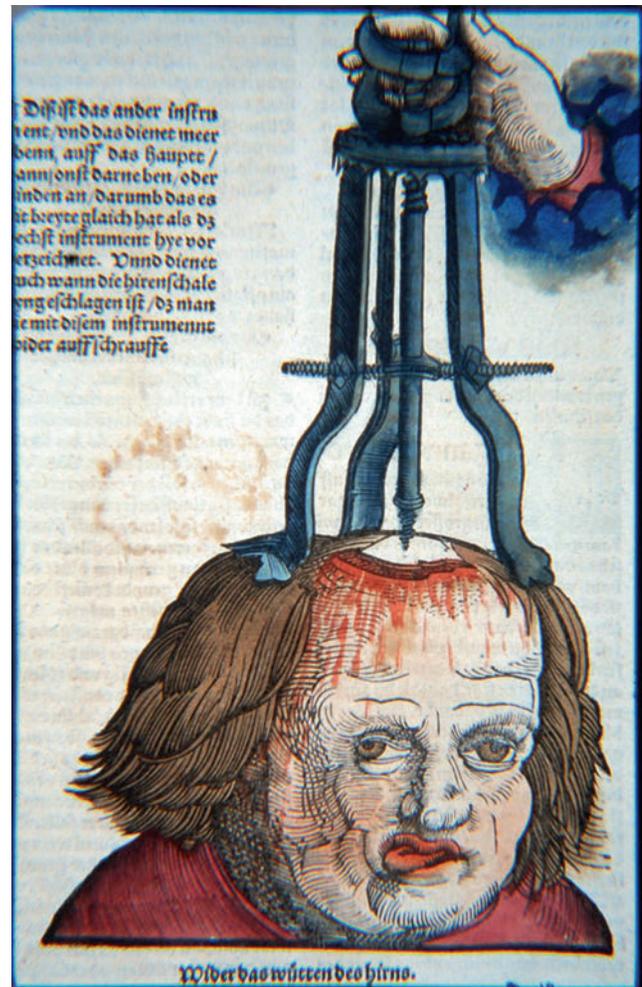

Fig. 58.1 Illustration from Gersdorff's classic surgical work⁵ in which he shows the technique of elevating a depressed skull fracture. He then forms a cranioplasty made from wood wool mixed with wine and wood oil to place back into the surgical defect. (Image courtesy of the University of Alabama Library, Reynolds Collection, Birmingham, Alabama.)

trephined, then repaired with gold or silver cranioplasties. These cranioplasties were well placed and contoured, and the patients clearly survived the surgeries with well-healed implants. Whether gold or silver was used appeared to be determined by the patient's social class. Metal plates of other types have also been advocated for use in repairing skull defects, as will be seen (► Fig. 58.2).

The concept of cleaning and replacing autologous bone in a craniotomy dates back to the brilliant French surgeon Ambroise Paré (1510–1590). Paré was performing autologous cranioplasties 500 years ago. His book *La Méthode Curative des Playes et Fractures de la Tete Humaine*⁶ contains an excellent description of the repair of skull fractures. Discussing the management of a large injury of this type, he noted that the bones were removed, and then he “turned them around and replaced them.” This technique of flipping over the bone flap is now in common use around the world. Paré also noted that he rarely covered cranial defects except those in the middle of the forehead, where for aesthetic reasons he used

Fig. 58.2 Early example of a successful cranioplasty (Peru, ca. 400 AD). The patient survived, as evidenced by the well-healed in situ cranioplasty made from a gold inlay. (Image courtesy of the Museum of Gold, Lima, Peru.)

plaster. For postoperative protection of the skull, Paré designed a molded leather helmet.^{6,7} One of the earliest illustrations of a “metal plate” cranioplasty appears in a book by Bellosté, *The Hospital Surgeon*.^{8,9} In both the French and English editions, published in the early 18th century, a frontispiece shows a surgeon placing a lead plate cranioplasty. In the text, Bellosté describes the procedure: “[W]hen the dura mater is uncov’r’d I prepare a plate of lead very thin, and very smooth, pierc’d it holes in several places with an inequality, cut and fitted to the bigness of the opening.” Interestingly, Bellosté observed that some patients reported discomfort around the cranioplasty site when the weather turned to extremes of hot or cold—“symptoms of the trephined”—a complaint still echoed today by patients in whom artificial and especially metal cranioplasty materials are used (► Fig. 58.3).

The use of skull bone material from nonhumans for cranioplasty dates back to at least the middle of the 17th century. In 1682, Job Janszoon van Meekerren (1611–1666) reported the case of a Russian soldier who had sustained a skull defect as a result of a war injury.¹⁰ An imaginative surgeon, he performed a cranioplasty with a piece of dog calvaria. Subsequently, the Catholic Church learned of this treatment, found it in violation of canon law, and ordered the dog bone to be removed. If the bone was not removed, the patient would be excommunicated. Unfortunately, we have no long-term follow-up of this case (► Fig. 58.4).

John Woodall (1570–1643) was an early advocate of the use of cleaned and debrided bone to close a cranioplasty defect. In

Fig. 58.3 Frontispiece engraving from Bellosté’s *The Hospital Surgeon* showing an 18th century surgeon performing a “lead plate” cranioplasty for a skull defect.⁸

The Surgeon’s Mate, published in London in 1617, Woodall stated that cleaned, fractured bone could be replaced without difficulty.¹¹ Woodall commented, nearly 400 years before the advent of high-speed pneumatic motors, that young surgeons who wished to trephine should practice first on the skulls of calves before attempting the procedure on a human skull—a remarkable early insight (► Fig. 58.5).

Over the years, a long list of foreign materials have been used to repair skull defects. In 1874, Ella reported a case of head injury in the South Seas in which the natives used coconut shells to repair the cranial defect.¹² ► Table 58.1 lists some of the materials used to repair defects over the course of the last two centuries.

58.2 Techniques of Cranioplasty

A cranioplasty is a procedure for repairing a defect of the calvaria. It can be accomplished in various ways. A successful cranioplasty is one in which the cranial defect is repaired and then heals and grows with the child in the anatomically and aesthetically most appropriate fashion. In the young infant (younger than 1 year), one can leave a cranial defect of up to 2 cm

Fig. 58.4 An unusual 17th century case reported by Meekeren on the use of a dog skull bone cranioplasty to repair a skull defect in a Russian soldier.¹⁰

open; as long as the dura and pericranium are intact, bone will commonly fill the defect. In older children, spontaneous repair becomes less likely, and substitutes and replacements for the missing bone must be considered.

In the management of craniofacial defects, the location is important. Defects in the frontoglabellar region require much more attention to detail than a defect behind the hairline. Contours, healing scars, alignment of eyebrows, and orbital dystopia all are important factors to be considered. Cranial defects can result from trauma, be congenitally acquired, or arise from infectious processes. Each of these etiologies has distinctive implications in both the timing and type of cranioplasty repair.

58.2.1 Preparation of the Cranial Defect

The preparation of a cranial defect remains the same in all cases, no matter what the source of the defect. The surgical bed must be clean and free of debris of any kind. Both the surgical bed and the overlying surgical flap must be well vascularized. Without these conditions, neither the flap nor the implant will heal. Preoperative planning has to take account of the nature and course of the scar, particularly so in cases of previous trauma. In many cases, it is best to incorporate the previous scar

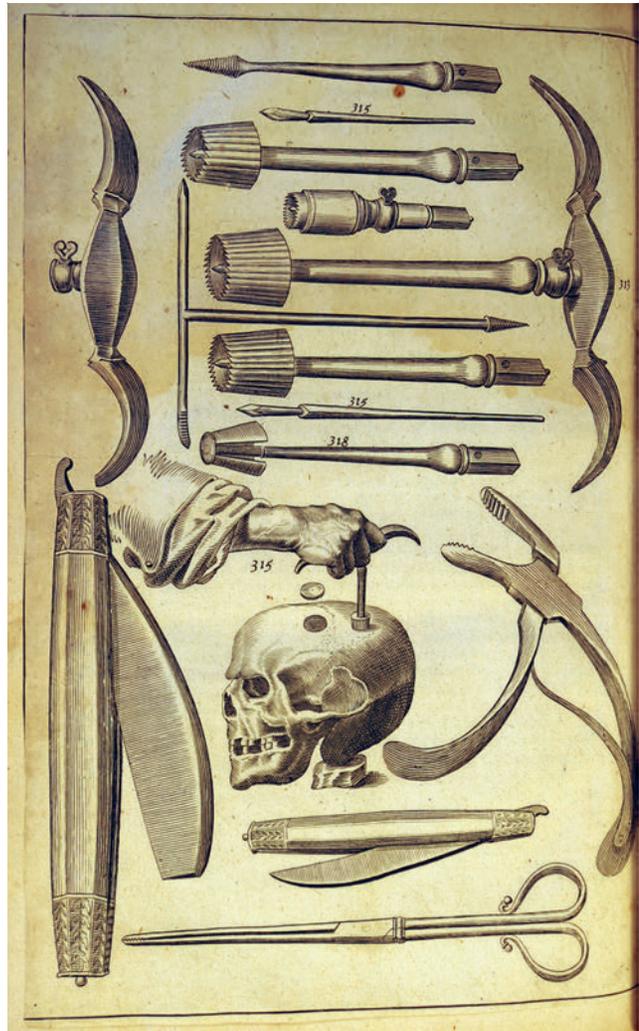

Fig. 58.5 Early surgical engraving from Woodall's *The Surgeon's Mate* showing typical surgical instruments used for trephination and the repair of skull defects in the 17th century.¹¹

Table 58.1 Materials used to repair skull defects during the course of the last two centuries

Author	Year	Material
Jaksch	1889	Eagle bone
Grekoff	1895	Calf scapula
Henschen	1916	Buffalo horn
Rehn	1912	Ox horn
Seydel	1889	Tibia
Keen	1905	Harvested bone chips from nearby skull
Kappis	1915	Rib grafts (first use)
Brown	1917	In situ split rib grafts (first use)
Mauclair	1914	Iliac crest bone
Roepke	1912	Bone from the scapula

into the repair. Because parallel scars can disrupt blood supply and cause a flap to slough off, parallel incisions should mostly be avoided. If possible, it is best to keep surgical incisions and scars in hair-bearing areas.

In the case of craniofacial reconstructions in the vicinity of the frontal sinuses, it is extremely important to cranialize the sinus and in some cases to obliterate it with a pericranium flap. The frontal sinus does not typically become developed until the age of 3 to 4 years. When the skin flap is elevated, the pericranium is brought up as a second layer, with its vascular pedicle kept intact. This vascularized pedicle flap can be easily rotated into a number of different positions to cover defects and the frontal sinus. Bone edges that are to be incorporated in the repair have to be “freshened up”—that is, cleaned and debrided of any scar tissue or debris. The edges of the cranioplasty should be lightly burred with good irrigation to provide a fresh vascularized edge. We have switched to the use of “resorbable” bone wax for bone edge bleeding. In our experience, the older formulas of bone wax inhibited solid bony unions by blocking good osseous integration. Meticulous hemostasis and the gentle handling of soft tissues are always obligatory.¹³⁻¹⁶

58.2.2 Use of Autologous Bone in Cranioplastic Reconstructions

Autologous bone is always considered first as the primary repair material in cranial defects. Autologous bone heals best, will grow with the child, and has the lowest incidence of infection and extrusion.

Essentially four types of autologous bone are available to the neurosurgeon for reconstruction: (1) split calvarial bone grafts, (2) costochondral rib grafts, (3) iliac crest, and (4) fibula grafts.

In the management of open depressed skull fractures, it appears to be common practice around the world to discard the traumatized bone flap and at a later date repair the craniotomy defect with some form of artificial implant.¹⁶⁻²² For the last 27 years, the author has routinely removed the traumatized bone, cleaned and debrided it, and then placed it back (see below for technique). This technique has virtually eliminated the need for a secondary artificial cranioplasty, particularly in infants and children. Avoiding the placement of foreign material, such as methyl methacrylate, clearly reduces the rate of infection; in addition, we have found that such repairs deteriorate with time, and in infants and children, the skull can outgrow the plate, necessitating still more surgery.²³⁻²⁷ Other late-term complications include flap migration and sinkage plus painful symptoms associated with barometric and temperature changes, also referred to as the “syndrome of the trephined.”²⁸

The neurosurgical practice of discarding the “contaminated” bone is actually a relatively recent practice introduced around the time of the First World War. The practice was fairly well entrenched by the time of the Second World War. A review of general neurosurgical textbooks shows that the practice is widespread and considered routine by general neurosurgeons. More recently, it has become a more standard practice among pediatric neurosurgeons to remove, clean, and replace the autologous bone flap and thereby avoid a later artificial cranioplasty.^{29,30}

Replacing Autologous Bone: Surgical Technique

The original scar (if present, as in an open depressed fracture) is used to expose the traumatized bone. A standard craniotomy is then performed with a high-speed pneumatic or electric drill (e.g., Midas Rex; Medtronic, Minneapolis, MN) and a “footed” attachment (e.g., B-5R). The bone flap is removed in a “cookie” fashion, with a 2- to 3-mm bone margin added to the outer edge. The surgical wound is cleaned, debrided, and vigorously irrigated to remove any debris and foreign material. The flap is then soaked in a 10% povidone-iodine (Betadine) and saline solution for 15 minutes, and then the Betadine is allowed to dry. Before the bone flap is repositioned, it is again washed and soaked in physiologic saline solution to remove any excess Betadine solution. The use of undiluted Betadine is actually toxic to bone and is not recommended. The bone is never autoclaved, frozen, or irradiated because these techniques denature the bone protein matrix and provide an extremely poor biological matrix for repair. In those rare cases in which the bone flap is accidentally dropped on the operating room floor, this same technique has been used with no deleterious effects. To reiterate, bone wax (we now use only a bioresorbable wax) is used sparingly to stop bleeding. Many years of personal experience with craniofacial operations has revealed that bone wax, when placed into the diploë space, retards natural bone growth and osseous integration and can also act as a potential nidus of future infection. Our preferred technique is to place sterile sponges (Gelfoam; Pfizer, New York, NY) soaked in thrombin (or sometimes Avitene; Bristol Healthcare, New Delhi, India) against the bleeding bone with pressure. This material is removed once hemostasis has been obtained. To further enhance bone healing, we stabilize the bone flap with resorbable miniplates. We routinely administer antibiotics to these patients for a 48-hour period postoperatively; the antibiotics used are suited for skin organism coverage (e.g., oxacillin or nafcillin).

The rigid fixation of bone flaps is critical in the pediatric population. In the late 1980s, the use of metallic fixation plates became the technique of choice. Unfortunately, over time, we have learned of potential problems, with plates migrating and fixation screws backing out, among other issues. In children whose intracranial pressure may be increased (e.g., those with a craniofacial syndrome, such as Crouzon syndrome), the use of metallic plates is not the best choice. At later reoperations in several children, we found that the metallic plates had migrated intracranially, and some were actually within the dura or brain parenchyma.³¹⁻³⁴ Similar problems have resulted from the use of wire in young children. As a result of these issues, our surgical team now uses only bioresorbable plates and sutures (e.g., Vicryl or Nurolon; Ethicon, Somerville, NJ) to stabilize the flaps. These plates are typically resorbed by hydrolysis over a period of 8 months to 1 year. Because of their higher profile, the family should be made aware of them; parents notice them right away, typically when first bathing their child. We have also had several cases in which sterile granulomas have developed over the plates. The granulomas are almost always sterile, and to date we have had no infections, nor have any required surgical intervention. The plate granulomas typically resolved over 2 to 3 months. If a granuloma is red and tender, then infection has to be considered, but in our experience to date we have not encountered an infected plate.³¹⁻³⁴

Split-Thickness Calvarial Bone Grafts

In the growing child, the use of native materials for craniofacial and traumatic repairs remains the gold standard. The human skull, with its natural contours, provides the best source of bone for repairs.³⁵⁻³⁷ The skull has a natural mirror image that allows the surgeon to harvest calvarial bone, bone that often possesses a contour that closely matches the defect. In most children, by the age of 3 years the skull has become bilamellar and can be split along the diploë to obtain two pieces of bone, one placed in the defect and the other in the donor site. With a soft, malleable piece of metal, a template of the defect is designed and applied to the contralateral skull in various positions until an area is located that closely matches the defect to be repaired. The donor graft is always made 3 to 4 mm larger than the defect. This allows for the bite of the craniotomy drill and gives additional trimming room for positioning the donor graft. The flap is elevated with standard craniotomy techniques and copious irrigation so that the heat generated by the craniotome does

not burn the bone. As discussed above, the use of wax, other than resorbable wax on bleeding bone edges, is discouraged (► Fig. 58.6 and ► Fig. 58.7).

Once the bone flap has been elevated, there are a number of surgical techniques available for splitting the bone. In the very young child (younger than 2 years), a razor-sharp osteotome is used; it is handled much like a knife to “slice” the bone apart. We keep a special set of osteotomes that are used only for these procedures. The edges are routinely sharpened, and there can be no nicks or dings on the cutting edges. The osteotome set has to contain a number of different sizes and curves to be effective. Another option is the use of a No. 15 scalpel blade, again to “slice” the bone. The bone is held in the nondominant hand while cradled in a surgical towel. This is done to protect the hand in case the osteotome or scalpel should slip. The diploë does not develop until about 3 years of age, but there is usually some marrow space available, even in very young children. In older children, usually after the age of 3 to 4 years, the bone is thick

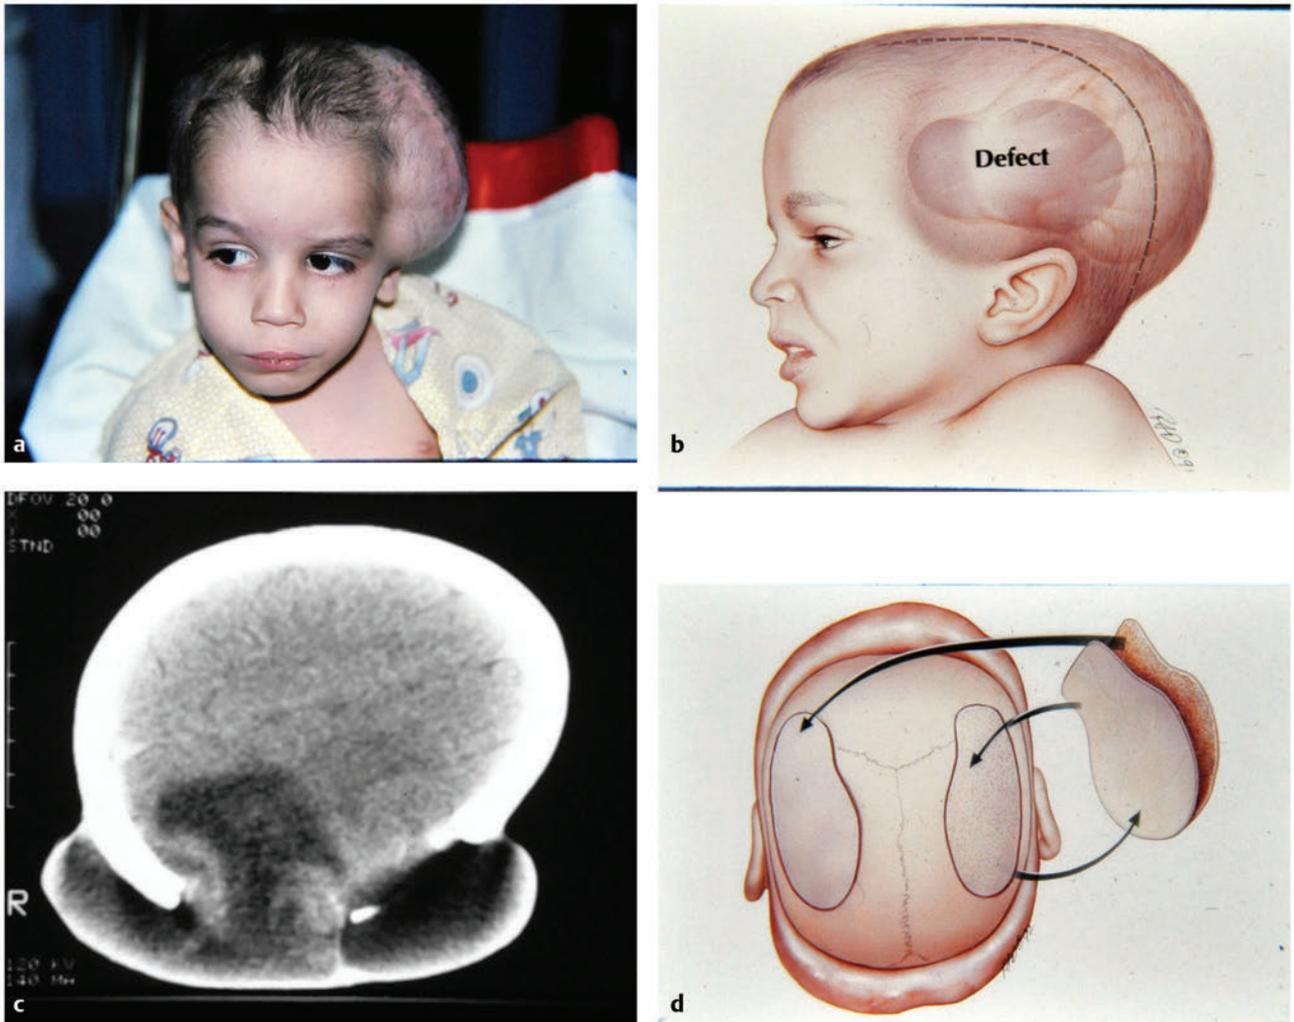

Fig. 58.6 (a) A 2-year-old boy who fell five stories and sustained a large parietal skull defect with a pseudomeningocele over the left parietotemporal region. (b) Artist's representation of the defect in the left lateral parietotemporal bone. An ideal case for harvesting a “mirror image.” (c) Axial computed tomographic (CT) scan showing the large skull defect and resultant pseudomeningocele, which will be repaired with a split-thickness calvarial bone graft from the opposite side. (d) Schematic showing the split technique, with harvesting of a “mirror image” piece of bone from the opposite side. The flap is elevated and split along the inner table, and the inner table goes to the graft site while the outer table goes to the defect site. (continued)

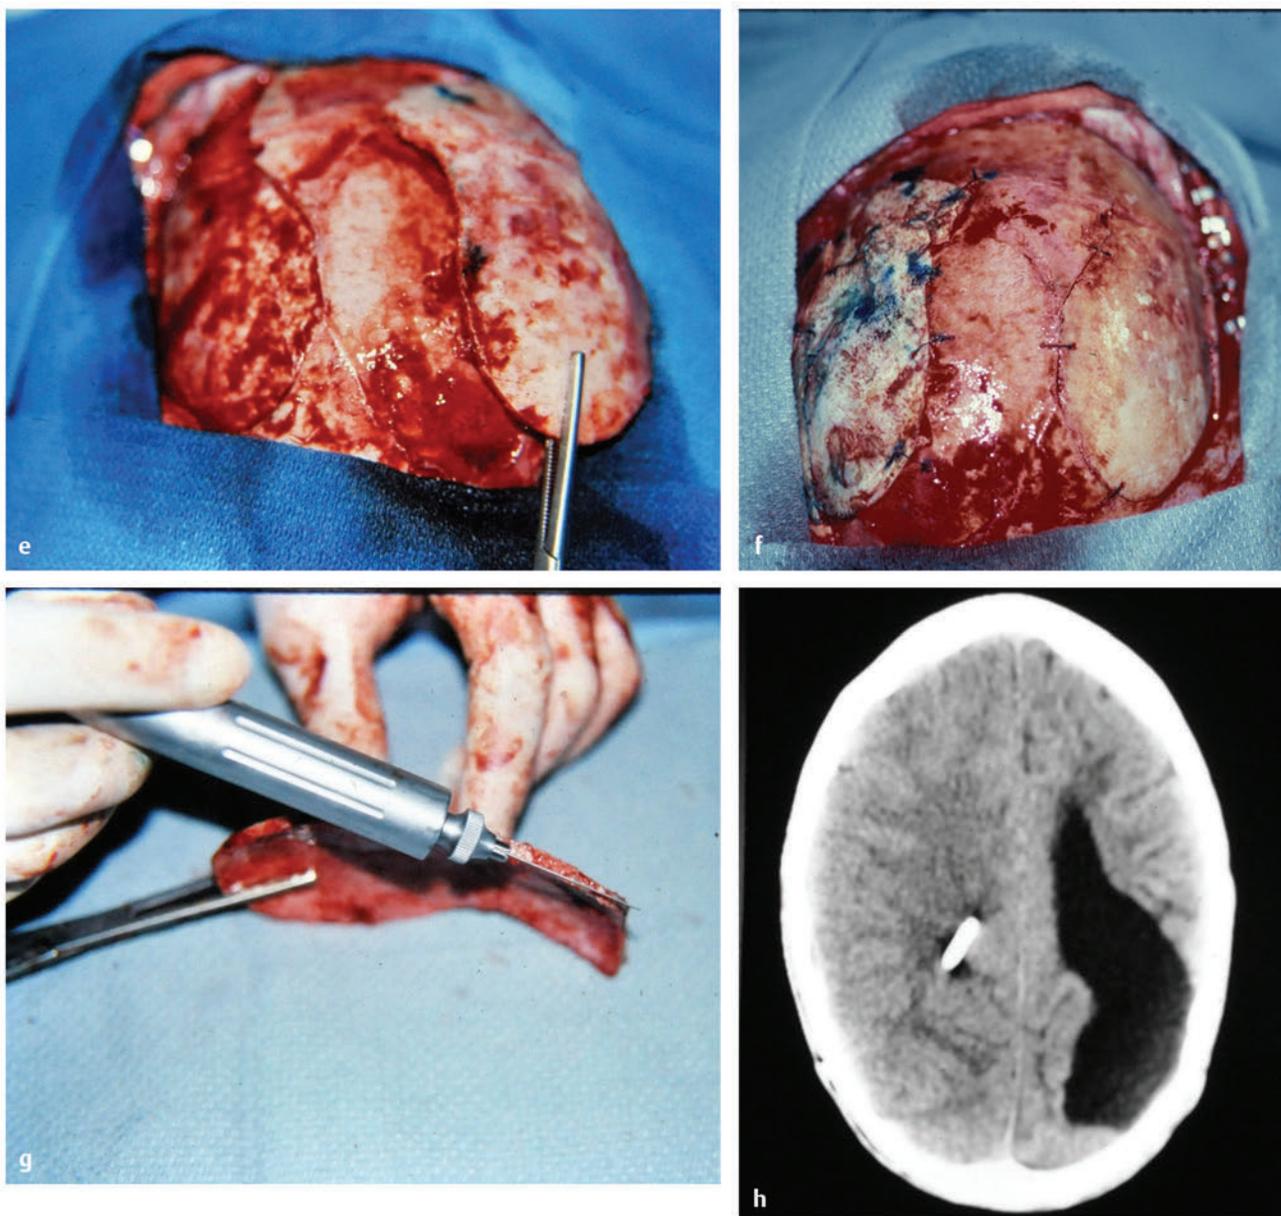

Fig. 58.6 (continued) (e) The full-thickness bone flap from the donor site (right parietotemporal region) is being elevated here and held by the Kelly clamp. (f) Both units of bone have been placed into position and anchored. The inner table has gone to the donor site on the right and the outer table to the defect site on the left. (g) A technique to split a full-thickness bone graft by using an oscillating saw and following the bone marrow space in the bone, just between the inner and outer tables of the skull bone. (h) CT of the patient done 8 years after the calvarial reconstruction with the split grafts shows the grafts now well incorporated. Additionally, no problems developed with displacement or infection in either bone graft. This patient has now been followed for more than 20 years, and there have been no further issues with the grafts.

enough to be split with fine, thin, high-speed tools such as the C-1 attachment for the Midas Rex. The splitting technique involves drilling a series of holes into the diploë space and then, in a side-to-side action, connecting the drilled holes. Depending on the diameter of the flap, curved osteotomes and reciprocating saws with flexible blades can also be helpful in splitting the bone. With some of the newer and thinner reciprocating/oscillating saw blades, we are now able to split bone in infants younger than 1 year of age. In the flap is very large, one can also cut the flap into two or four pieces, complete the splits, and then plate the units back together with miniplates (► Fig. 58.8 and ► Fig. 58.9).

The thickest bone for harvesting is over the frontal and parietal boss regions, and the thinnest is over the temporal regions—considerations to be kept in mind when bone is harvested. It is always desirable to create large bicoronal flap exposures when the need for large grafts is expected. In those cases in which additional bone contouring is necessary, we use what is called a “wagon wheel” technique. A full-thickness skull bone is elevated with the pericranium left on. The flap is then split, with the inner table going to the donor site. The outer table, with the pericranium kept moist and intact, is then contoured with a series of cuts that look like a “wagon wheel.” A circle cut is

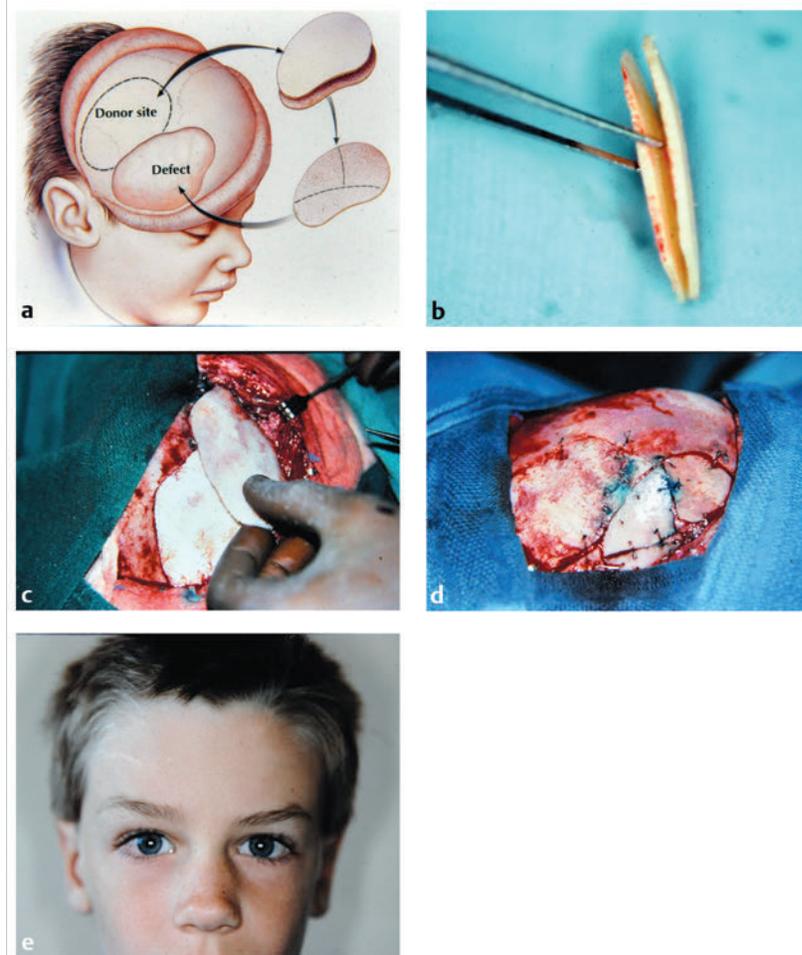

Fig. 58.7 (a) A 5-year-old boy who sustained a right fronto-orbital depressed skull fracture in a motor vehicle accident. He presented 2 years after the accident with a large right frontal skull defect. (b) After the bone flap is harvested, it is given to the plastic surgeon to create a split-thickness graft forming the two units of bone seen here. In this case, an oscillating saw was used with a “soft” flexible blade within the bone marrow. (c) The skull defect is exposed and debrided along the bone edges. Behind the defect, a craniotomy is marked matching the defect site. This unit of bone is elevated and split along the diploic space. One piece goes back to the donor site, and the other is cut and contoured to fill in the defect site. In this image, the donor site has been replaced, and the surgeon is marking out the cuts for the reconstruct of the forehead contours. (d) A view of the right side of the forehead showing the donor unit replaced posteriorly. Anteriorly, each of the bone units has been cut, contoured, and placed into position within the defect site. (e) The patient 3 years after surgery, during which time he maintained a symmetric forehead along with excellent orbital control. With now a 22-year follow-up, no relapse or loss of bone and no infection issues have occurred.

made in the middle, and a series of “spokes” are made from the circle to the edge of the flap. The pericranium is not cut, and the bone cuts are made down to the thickness of an eggshell. With gentle finger pressure, the bone can be fractured to the desired shape (► Fig. 58.10). This technique is particularly useful for desired bone contours in the orbits (roof and floor) and around the orbital rim (► Fig. 58.10).

Another technique for obtaining bone is the *in situ* outer-table craniotomy; it can be used in the older child and adolescent whose skull thickness is greater than 1 cm. The technique involves drilling a trough around the edges of the pre-designed bone template. The trough is carried into the diploë but not through the inner table. With the use of very sharp curved and straight osteotomes placed within the diploë, the outer table of bone is lifted off, with the inner table left intact to serve as the repair material. A reciprocating/oscillating saw can also be helpful once the plane has been developed with the application of osteotomes. In another technique, a Gigli saw is placed in the diploë, and by following the diploë, one can elevate the outer table. This technique has been particularly popular with plastic surgeons. It is necessary, however, to keep in mind the risk that the osteotome and/or saw blade can plunge through the patient’s thin bone into the brain, so extreme caution needs to be exercised when these techniques are used (► Fig. 58.12). The use of split-thickness grafts has many advantages and remains the standard for

Fig. 58.8 A split graft between the two tables of bone is made with a fine cutting tip (Midas Rex C-1 or X-1) placed into the bone marrow with a series of full penetrations. These “plunges” are then connected in a side-to-side motion. Copious irrigation is supplied to keep the bone from being burnt.

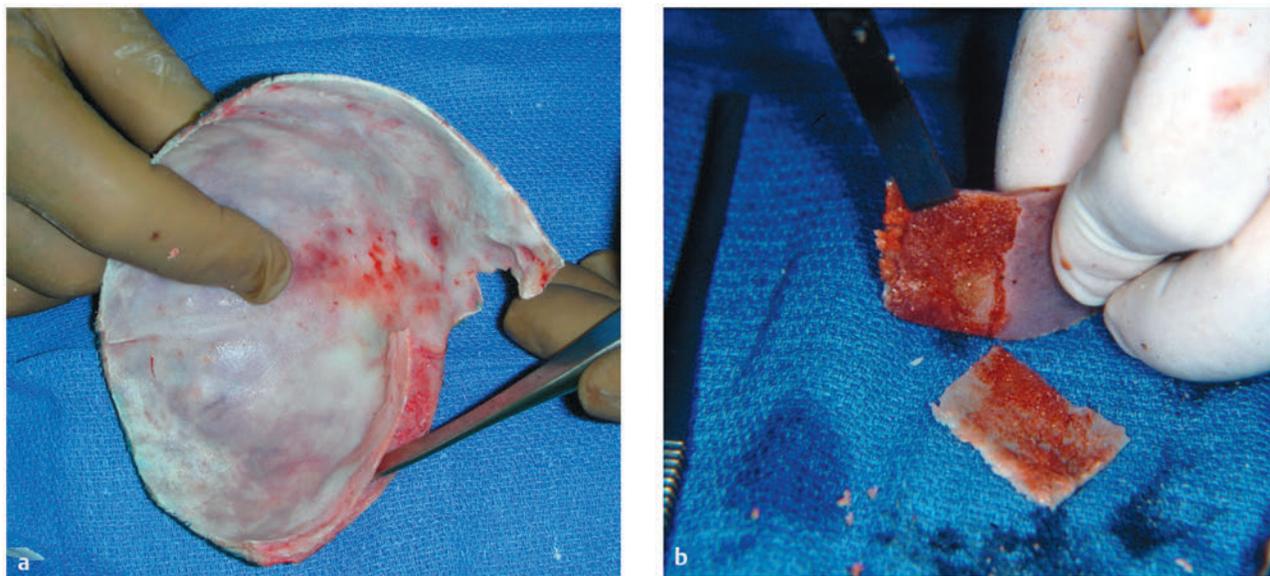

Fig. 58.9 (a) Technique of using a sharp osteotome like a “knife” and splitting along the marrow space. This is being done in a 6-month-old child with plagiocephaly for extra graft material. (b) In a very young child, the bone can be easily split with a fine sharp osteotome or a No. 15 scalpel blade. The instrument is used like a knife to split bone in the marrow space.

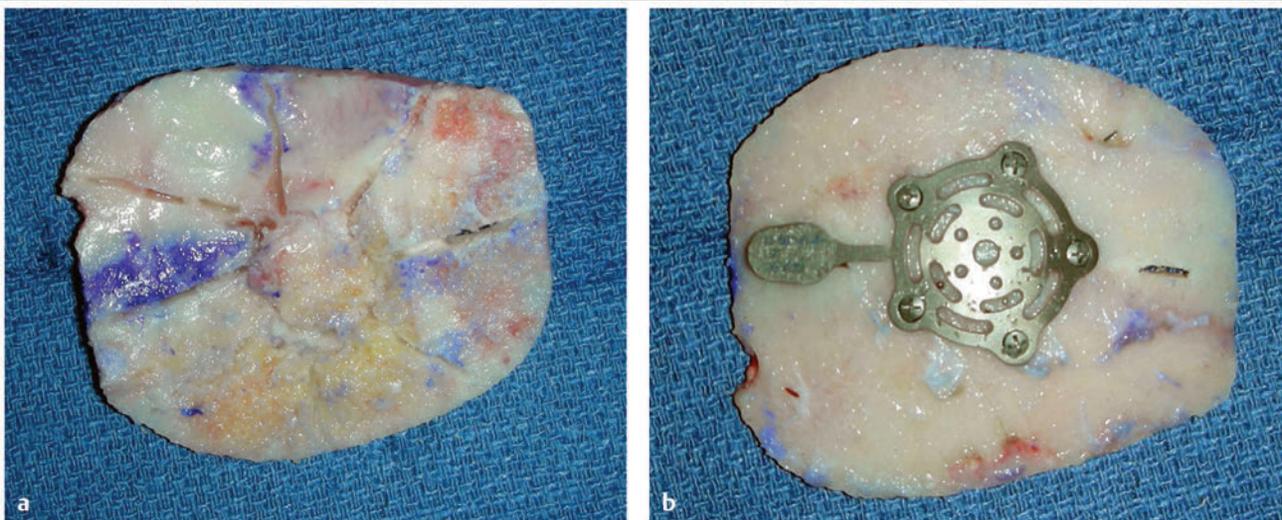

Fig. 58.10 (a) The “wagon wheel” technique for contouring bone. The bone is first split along the diploë, as described above. The pericranium has been left on the outer table. On the side opposite the pericranium, the “wagon wheel” cuts are made—a center circular cut and then a series of radiating cuts deep to the pericranium. The cuts are just made to the edge (i.e., an egg shell thickness). The pericranium holds the bone together, and with just gentle finger pressure the bone can be shaped in the desired contour. (b) With a fine bur or cutting tool, the radial cuts are made on the side opposite to the pericranium. The cuts are made in such a fashion that an “egg shell” thickness is left at the end of the cutting.

craniofacial repairs. The infection rate is very low in these cases. The risk for rejection is virtually nonexistent. The natural bony union that results grows with the child, an important consideration in younger patients.

Rib Grafts

Rib grafts have long been popular with plastic surgeons and have been used in various types of cranioplasties.^{38–40}

Furthermore, these grafts are a source of ample material that can be obtained easily and with low risk to the patient. An advantage of ribs is that they can be obtained from the patient in any of a number of surgical positions. On the anterior chest, the fourth through the sixth ribs are accessible; on the posterior chest, the eighth through the tenth ribs are accessible below the scapula; and in the lateral position with the patient’s arm abducted, the fourth through the eighth ribs are easily accessible.

Fig. 58.11 (a) The “spiral” technique for contouring bone. A full-thickness piece of calvarial bone of the desired size is harvested from the opposite side. As illustrated here, it is harvested from the right side, with the template designed on the left. (b) A full-thickness bone graft that has been elevated and split shows both the inner and outer tables. The inner-table graft on the right will be placed back in the donor site. The outer-table graft on the left will be contoured with a “spiral” technique. (c) The outer-table bone graft has been cut with a high-speed drill starting at the outer edge and then carried in a circular fashion to the center. With just gentle finger pressure, this split bone graft can be contoured to fit just about any area with a contour, such as the forehead or orbital roof and floor.

The graft site is exposed and prepared in standard fashion with fresh bone margins. The area is measured and the graft size determined. The rib grafts are harvested by making a skin incision directly over the ribs selected. This incision is carried down to the rib periosteum with a monopolar cautery and a fine needle tip on a low-current setting. The periosteum is separated from each rib with a Key-type periosteal elevator. As the rib is elevated, the neurovascular bundle and underlying periosteum and pleura are left intact and gently stripped away with a pigtail rib separator. In determining the rib length that is to be removed, be sure to allow *an additional 5 to 8 mm for the bending and contouring*. Each end of each rib is cut, removed from the field, and split longitudinally with a sharp osteotome, yielding two pieces that can now be bent and contoured with a Tessier rib bender. Because ribs are malleable and fracture easily, the splitting must be done slowly and carefully. Rather than apply a mallet to the osteotome, it is better to use the os-

teotome like a knife blade and slowly work your way through the rib in a “knifelike” fashion. The ribs are then positioned at the recipient site and shaped to fit the size and contour of the defect. It is desirable to create a graft whose height and contour are slightly exaggerated because there is typically some collapse and resorption of the graft over time.

Because rib is the most malleable of the materials available, it is particularly applicable to reconstruction around the orbits and over the forehead. In very large cranial defects, the “wire link fence” technique of Munro and Guyuron³⁹ can be useful. With a series of split ribs, the bone is woven together in a wire link fashion and then positioned as a craniotomy flap. The only problem with this technique is that over time the ribs can take on a “washboard” appearance, which is quite undesirable as far as aesthetics are concerned.

Some “pearls” to keep in mind in harvesting ribs and using them in reconstruction follow:

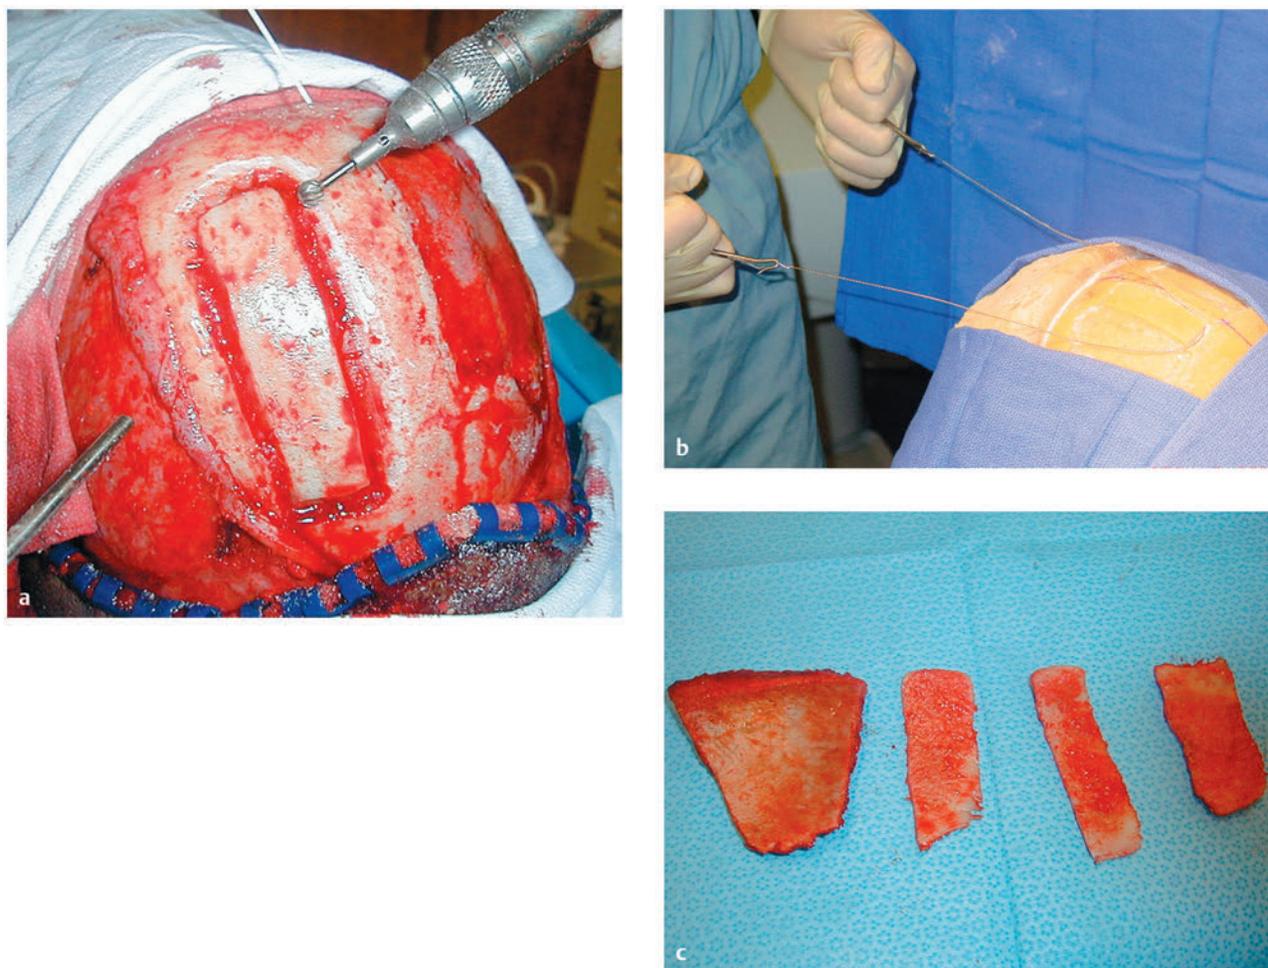

Fig. 58.12 (a) Technique for harvesting an outer-table bone graft. A trough is made in the skull bone to the level of the diploë with a round bur. (b) A Gigli saw is placed within the diploë, and the surgeon “travels” the saw within the diploë space. This technique requires some skill in using a Gigli saw, but it can successfully produce large pieces of graft bone of different contours and shapes. (c) Four split grafts obtained from a single patient by outer-table harvesting with the Gigli saw technique.

Pearls

- Never take more than two adjacent ribs; otherwise, a “flail” chest may develop.
- Always attempt to keep the rib periosteum intact because this will allow a rudimentary rib to form in the donor site.
- Should the pleura be violated and a pneumothorax occur, place a 10F red rubber catheter over the repaired pleura defect during a Valsalva maneuver. The red rubber catheter is placed in a low water-sealed suction apparatus with 20 mL of water pressure applied. Once a chest X-ray shows the pneumothorax to be resolved, the tube is removed and an occlusive dressing is placed over the wound. The tube can usually be removed in the recovery room.
- In shaping the ribs at the recipient site, exaggerate the contour to allow for the resorption that will naturally occur.
- In female patients, the best exposure for taking the rib is through an inframammary incision. Such scars are well hidden and heal nicely.

Despite the usefulness of rib grafts, given the problems with resorption and the “washboard” effect that can occur with lattice-type reconstruction, this technique should be reserved for those cases in which skull bone is not available. It has been our experience that the rib grafts look best in the initial 2 to 3 years; by 10 years after repair, the aesthetic outcomes can be much less gratifying.

Iliac Crest Bone Grafts

The iliac crest has always been used by neurosurgeons as a donor site, historically in connection with anterior cervical discectomy. A fair amount of bone can be obtained—usually without entailing significant morbidity. The patient’s most common complaint is of pain at the belt level postoperatively. The major problem with iliac crest bone is that the available bone is limited in quantity and possesses minimal contour. Despite these reservations, the iliac crest still remains an adequate source of bone in situations in which skull bone or rib is not available (► Fig. 58.13).

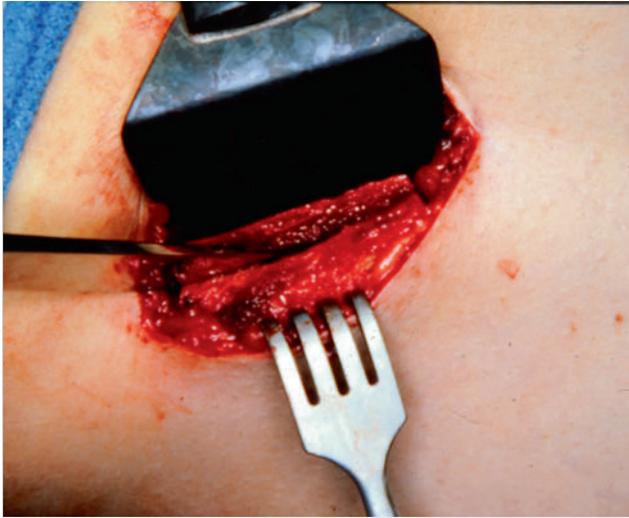

Fig. 58.13 Harvesting an iliac crest bone graft. The iliac crest is exposed, and the split graft is lifted out.

To harvest iliac bone, the iliac crest is identified. A linear incision is then made 1 to 2 cm “below” the crest. Avoiding the crest location reduces excessive scar formation and, more importantly, the “belt level” pain plus scar, which can be quite debilitating. The incision is carried down through the subcutaneous tissue to the muscle. The aponeuroses of the internal and external oblique muscles are incised, and the transversalis fascia is exposed. This fascia is then excised from the internal table of the iliac bone. The abdominal contents are retracted medially. If the subperiosteal plane is followed, up to 4 to 5 cm of iliac crest can be exposed. With osteotomes and an oscillating saw, a premeasured unit of bone is harvested. The site is then packed with Surgicel (Ethicon, Somerville, NJ) or Gelfoam soaked in thrombin. Large emissary veins do sometimes occur in the bone, and these can be controlled with bone wax. A closed Jackson-Pratt drain is tunneled subcutaneously away from the surgical site and removed after 24 hours. Fascial layers are reapproximated and closed and a multilayer closure accomplished. Iliac bone is cancellous, like calvaria, and is less likely than rib to resorb. Iliac bone revascularizes much more rapidly than rib, leading to a quicker incorporation into the surrounding skull bone. The disadvantages are mainly that iliac bone is more brittle, less malleable, and more difficult to contour than rib. Iliac crest bone is not a good source for grafts to be used in regions such as the vicinity of the orbit, in which aesthetic contouring is important. This technique is also age-dependent; it should not be used in children younger than 5 to 6 years.

Summary of Autologous Bone-Grafting/ Cranioplasty Techniques

In order of preference, bone is harvested from the following sources:

- Cranial bone
- Rib
- Iliac crest

Cranial bone clearly has the most advantages; it is typically close to the operative site and offers different contours along with often-needed generous portions of bone. A second incision is not required, and secondary resorption is minimal. Ribs are a good secondary source when calvaria is not available. Ribs can be split, and their innate malleability provides good contouring. When using rib, one also has to keep in mind its disadvantages, which include resorption and “washboard” effects that can develop as the child ages. Pneumothorax and painful incision sites can add further morbidity at the harvest site. A tertiary source of bone remains the iliac crest. Because it is cancellous, it is not resorbed to the same extent as rib. However, its lack of contours and brittleness make an aesthetically acceptable repair less likely than when rib or calvaria is used, particularly around the orbits and forehead.

58.2.3 Use of Implantable Cranioplasty Materials for Cranioplasty Reconstruction

Over the years, neurosurgeons have searched for the ideal material for the repair of bony defects in the skull. The ideal characteristics of implantable materials for use in reconstruction of the calvaria were outlined by Firtell and Grisius¹⁶: (1) inertness, (2) malleability, (3) availability, (4) radiolucency, (5) sterility, (6) durability, (7) nonconductivity, (8) biocompatibility, and (9) low cost. In the infant and child, another important factor is (10) the ability of the material to grow with the child.

Beginning in the late 1980s, our neurosurgical service made significant strides in avoiding the use of foreign materials in the growing child. Over the years, it has been a rare occasion when we are not able to find autologous bone for the repair of skull and facial/orbital bone. Metal implants conduct heat and cold, and patients were often bothered by them, especially during weather changes. Belloste pointed this out in 1713⁸ in connection with a child in whom he had placed a lead craniotomy plate. Acrylic resins have been popular over the last several decades for cranioplasty; however, it must be remembered that these materials are not incorporated biologically and hence always remain “foreign.” Often overlooked is the concept that these materials do not grow with the child and can over time become “floating islands” in the skull. Furthermore, foreign materials of any type degrade with time and always entail an increased risk for infection. Probably most disturbing to the pediatric neurosurgeon (and family!) is the return of a child several years after repair whose implant material is now free-floating (i.e., no longer in contact with the calvarial margins) and providing none of the desired intended protection and stability. However, for the sake of completeness, some of the cranioplasty materials available to the neurosurgical community are discussed, with a focus on their pros and cons.

Methyl Methacrylate

Methyl methacrylate (MMC) is among the most commonly used cranioplasty materials in the neurosurgical community.⁴¹ When combined with a wire mesh or titanium plates, it

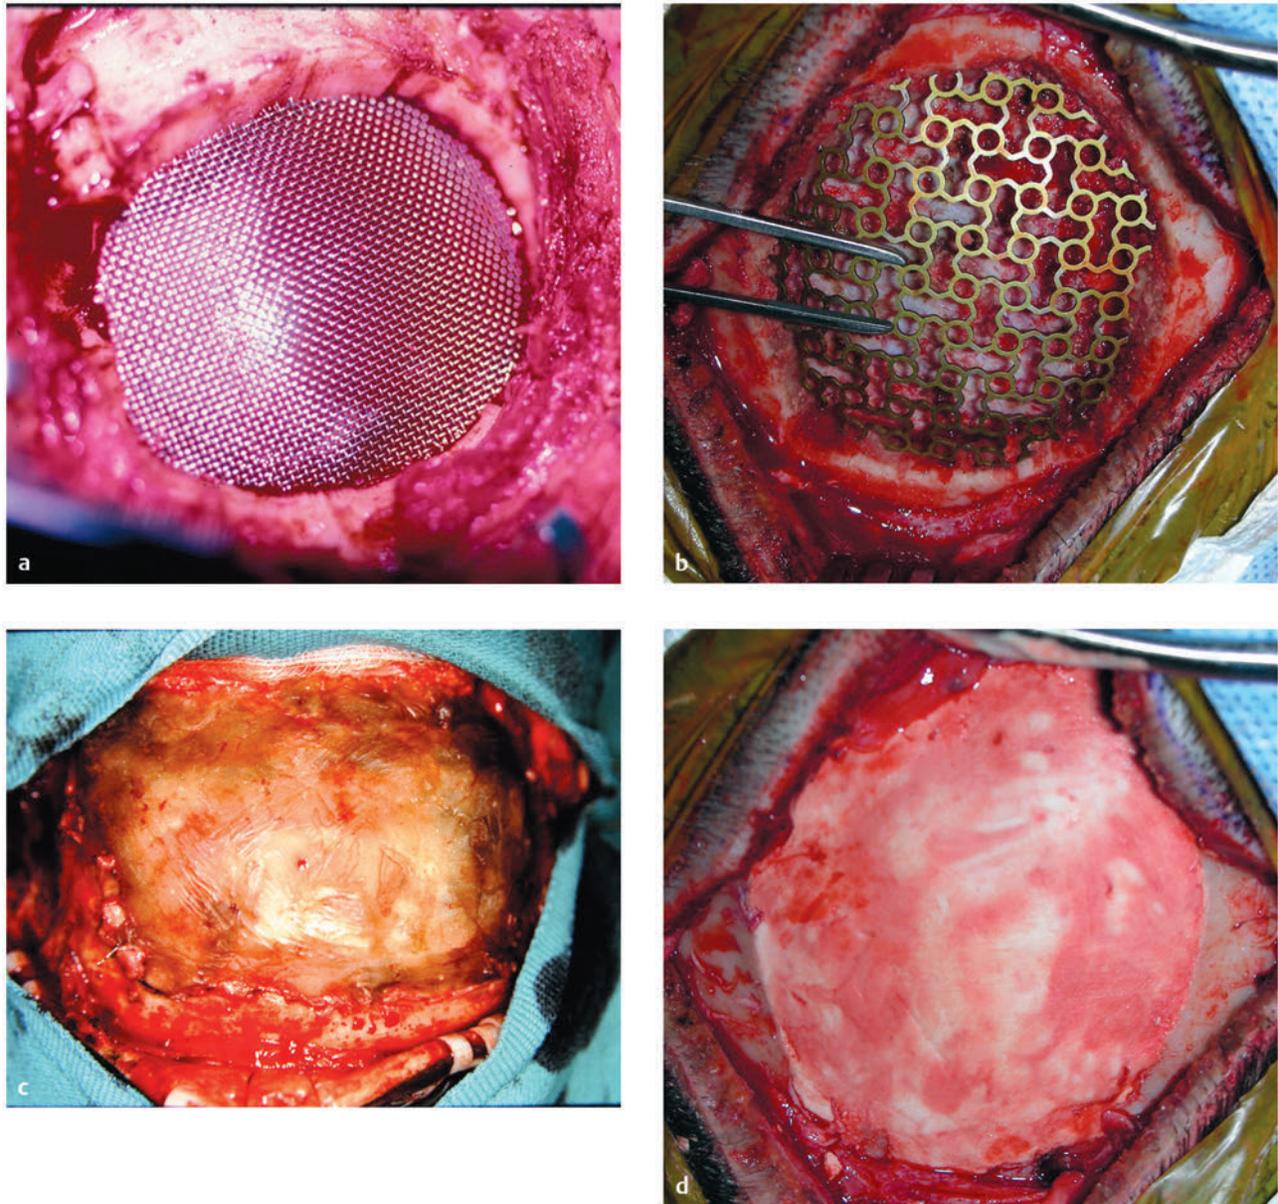

Fig. 58.14 (a) A wire mesh template has been placed into the debrided craniotomy site. (b) A titanium mesh plate is contoured and placed into the defect, with enough distance allowed over the top in which to place the implant material. (c) Methyl methacrylate has been applied over the mesh material, with the material contoured to the skull surface. (d) In this case, a “bone source” material has been layered over the mesh to provide the necessary contour.

becomes durable and malleable and can be shaped as needed. The technique for constructing an MMC implant is straightforward. The graft site is prepared as described above. The bone edges are freshened and any fibrous material removed from the bone edges. The bone edges should be bleeding slightly, with any heavier bleeding controlled with Avitene or Gelfoam (not bone wax). If dural tears are noted, they must be sutured and closed. The ends of the bones surrounding the defect are given a “step-off” edge with a squared-off bur tool attachment. It is on this bone ledge that the contoured wire mesh is placed. The step-off along the bone edge is a key design because the ledge prevents the wire mesh from slipping and penetrating into the

dura. This is particularly important in active children subject to falls during play. The mesh is shaped and designed to match the prevailing contour of bone but placed slightly lower to allow for the layer of MMC that will be placed over the mesh. If possible, the wire mesh should be made of titanium rather than stainless steel because titanium is stronger and less susceptible to deformation with direct impact. With the increased use of magnetic resonance imaging and computed tomography (CT), titanium causes less metallic artifact on scanning. However, in many parts of the world the cost of titanium is prohibitive, so the cheaper stainless steel mesh is still commonly used (► Fig. 58.14).

Fig. 58.15 (a) A 6-year-old girl had had a methyl methacrylate (MMC) plate placed 2 years previously. The plate became infected and over time was exposed. Here, necrosis of the overlying skin flap can be seen, with active purulence and exposure of the acrylic and wire mesh underneath. (b) The MMC implant was removed. No incorporation of the plate had occurred, and the wire mesh edges had eroded through the skin. The implant was removed and split calvarial bone grafts were placed. With a now 25-year follow-up, the grafts have survived well. (c) The patient 6 months after a split bone graft repair, with the original wounds well healed. We have followed this patient now for 25 years, and the grafts have remained stable.

MMC is provided as a powder and a liquid catalyst that are mixed to form a paste having a putty-like consistency; if applied when too liquid, it will run off the field. Using a moistened gloved finger and paying close attention to desired contours and height, the surgeon applies the paste in layers. Any rough edges are smoothed out before the material sets. Extra effort is needed to be sure that none of the edges of the wire mesh are exposed; failure to cover these edges can lead to erosion through the skin or penetration of the dura. As the MMC dries, it becomes extremely exothermic, so constant cool irrigation must be applied until the flap is completely dry; otherwise, the heat can injure the dura and underlying brain. A useful technique is to take a 5- to 6-cm ball of the MMC paste and hold it in one hand while irrigating the plate; by gauging the temperature of the paste as it sets, one can determine the stage of the setting process of the paste and how much heat is being generated in situ. Once the MMC has completely set, examine and remove any rough or sharp edges. These rough edges are easily removed with a high-speed round bur before closure. Before skin

closure, vigorous irrigation of the implant site is important to remove any remaining dust and debris.

In early reports of a large series of MMC cranioplasties, Rish et al¹⁹ documented a low incidence of infection (3.7%) and a low rate of cranioplasty loss (3.1%). However, a review by Blum et al²³ revealed that over the long term (i.e., more than 8 years, especially in the pediatric population), the failure rate becomes much higher; these investigators reported a 23% complication rate. In our own personal experience, as you reach the 20-year implant time, the combined risks for infection, extrusion, migration, and sinus tracts approach 80%. In the growing child, MMC is a foreign material, and its failure to grow with the child makes for a very undesirable situation. The exception is those rare situations in which there is not enough native autologous material, and then an MMC plate can be placed as a temporizing measure. As the child gets older and more autologous materials become available, the foreign plate can be removed and replaced with native material (► Fig. 58.15).

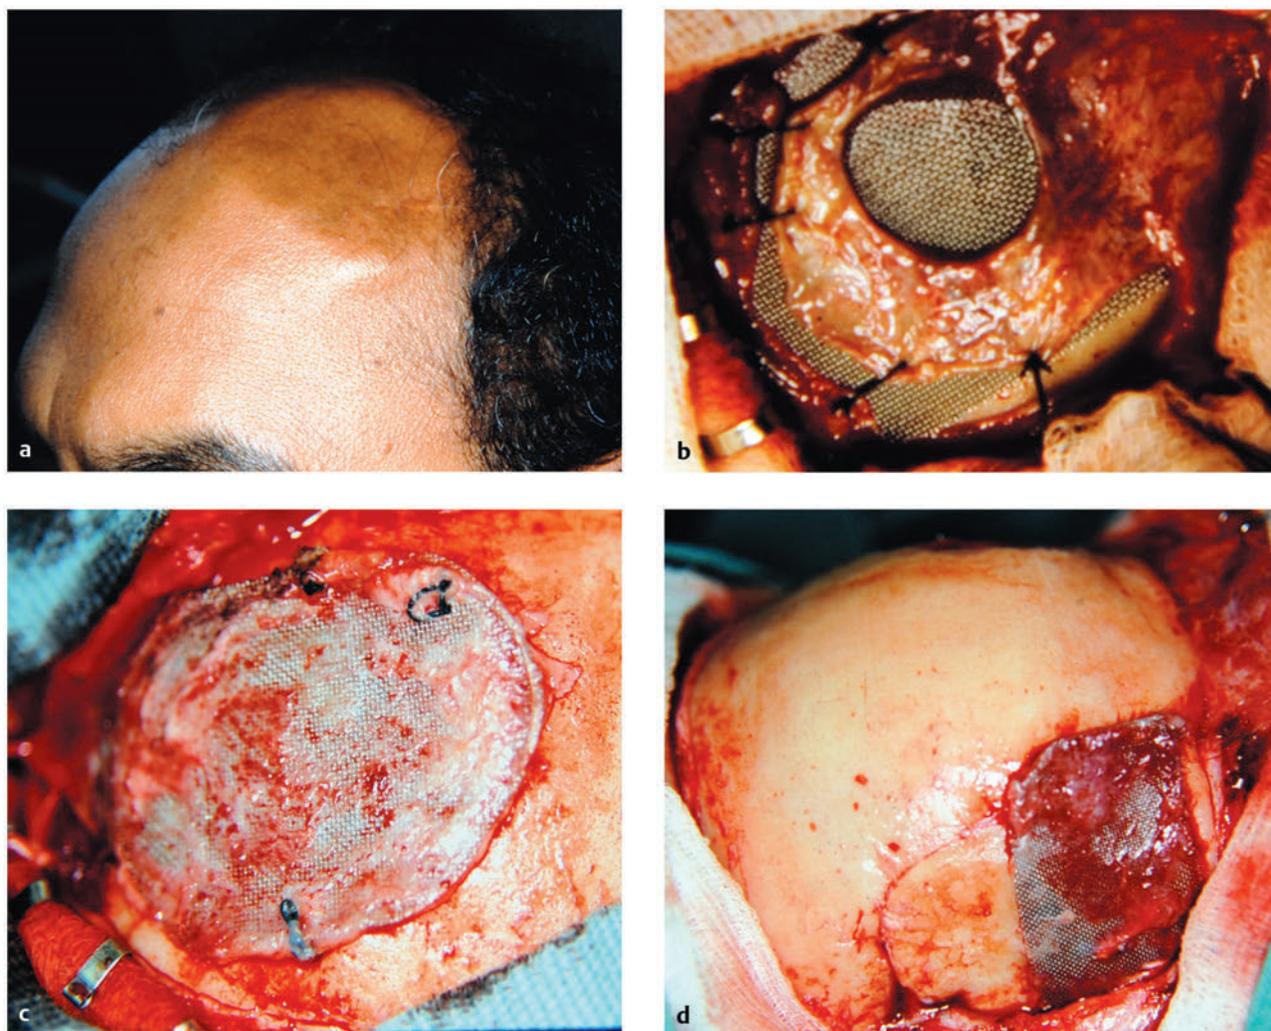

Fig. 58.16 (a) This patient had a wire mesh placed for a posttraumatic defect and presented 16 years later with a flattening of the implant after a minor blow to the head. (b) Multiple wire mesh implants were placed for posttraumatic defects. Eighteen years after placement, the mesh began to migrate into unacceptable positions over the skull. (c) A wire mesh cranioplasty was placed in the forehead for a traumatic skull injury. The patient developed a late-onset infection 12 years after placement of the wire mesh implant. (d) A mesh implant was placed in the right side of the forehead after a craniotomy flap infection. The patient presented 16 years later with the mesh eroding through the skin.

Other Cranioplasty Materials

Hydroxyapatite

Over the years, manufacturers have proposed a number of substitute materials as the “ideal” bone replacement. Although the initial results were encouraging, with time these materials gave rise to the same problems described above: resorption, infection, erosion, fracture, and extrusion. A material originally developed for use in maxillofacial surgery is hydroxyapatite, which is derived from native sea coral that is triphosphorylated under high pressure, then reaminified to form a matrix resembling that of bone.^{42–47} The concept was that when the reformatted hydroxyapatite was placed within a region that had bone, the matrix would be filled by an ingrowth of native osteocytes, blood, and bone marrow matrix. In other words, it was hoped that there would be natural osseous induction and osseous conduction into the hydroxyapatite. Studies by

Holmes and Salyer originally demonstrated up to 30% replacement with *in vivo* osseogenesis and osseous conduction.⁴² With the introduction of CAD/CAM (computer-aided design and computer-aided manufacturing) equipment, CT-designed units could be ordered that were premeasured to fit a craniofacial defect.⁴³ The theoretical advantages of this material led to initial enthusiasm. No donor graft was required, contoured pieces could be obtained, and the ingrowth of native bone substrates appeared to make this material ideal for the growing child. In reality, surgical experience in humans has shown that these ideals have not been realized in the same fashion as was seen in animal models. In the early 1990s, we had several cases in which this material was used, and unfortunately we had a 100% failure rate. In its reconstituted form, hydroxyapatite is hard to shape and extremely brittle—rendering it more susceptible to fracture and dislodgment in children.

A different formulation of hydroxyapatite material has been available in a paste format (e.g., Norian Craniofacial Reconstruction System; Synthes Maxillofacial, Palo Alto, CA; BoneSource; Stryker Leibinger, Porage, MI; Minix; Biomet, Warsaw, IN) The material is provided as a powder that, when mixed with a catalyst solution, forms a putty-like material.^{46,47} The paste is amenable to easy contouring and placement into defects. Our craniofacial team initially used this material for contouring and filling in trauma defects, especially around the orbits. However, having now followed these patients for 15 or more years, we have found higher than acceptable infection rates, along with skin extrusion. In several cases of reoperation, we noted an almost complete lack of bone conduction and integration. We also noted that with time, the paste tended to return to a powder form. In cases in which the paste was used to “contour” a surface, it formed only a veneer that with just mild trauma could easily be fractured. Postoperative seromas have also occurred around the implant material. With the present formulations, we do not share the enthusiasm of our plastic surgery colleagues for these bone cement/paste materials and have given up their use in our craniofacial reconstructions (► Fig. 58.17). The current recommendation is for the limited and selective use of these bone “replacement” products in the pediatric population.

Porous Polyethylene (Proplast I and II)

Proplast (a polymer of polytetrafluoroethylene and carbon filaments) been used extensively for years by our colleagues in maxillofacial and oral surgery. Its utility in craniofacial and trauma surgery has yet to be determined.^{48,49} The porous matrix is designed to allow ingrowth of the host's tissue and osteogenic and vasogenic material. Proplast I is made from a black porous carbon with added Teflon. Proplast II is a white carbon material to which Teflon and alumina have been added. Both types of Proplast are chemically inert, biocompatible, nonallergenic, and approved for implantation. Pore sizes range from 50 nm to 400 nm. The material is produced in a number of shapes and sizes. The proposed advantages of Proplast are several: (1) It can be carved to any desired shape and size; (2) with time, a fibrous vascularized tissue grows into the material and rapidly becomes stabilized next to the adjacent bone or soft tissue; (3) Proplast has been used extensively in the periorbital, nasal dorsum, zygomatic, and malar regions with good results. Our team has used it on occasion to fill defects of the calvaria in young children during craniofacial repairs in which opportunities for harvesting bone grafts were limited. With time, the material has been shown to have several disadvantages: (1) Because fixation to adjacent tissue takes time, Proplast can migrate; (2) if used in the very young child, Proplast does not become contoured to the surrounding structures as the child grows, making for a potentially unacceptable aesthetic result. Its use in the younger pediatric population (i.e., younger than 12 years of age) and the fact that it is being placed in children with normal, long life expectancies tends to give considerable thought before placing it in a child (► Fig. 58.18).

Silicone and Silastic Implants

Silicone has been used widely in craniofacial reconstruction.^{50–52} It is inert and well tolerated by the body, evoking only a rare

local inflammatory or allergic response. Silastic (Dow Corning, Midland, MI) implants are now available in various sizes and preformed shapes. The material is easily shaped or carved in the operating room; in the face, the aesthetic results initially can be quite good. However, with more than 25 years of experience, we have discovered that there are some significant disadvantages (► Fig. 58.19).

- With the passage of time, this material, particularly in growing infants and children, has a tendency to migrate and come to rest in less-than-desirable locations. Once placed, the implants do not withstand trauma well and can be displaced as a result of a blow to the head or face.
- In growing children, the material can eventually lose its contour to the surrounding structures.
- As an implanted foreign material, it always remains susceptible to infection.

Cadaver Bone

The use of cadaver bone as a cranioplasty material is long-standing. In principle, cadaver bone is supposed to provide a matrix for new bone ingrowth. In reality, this rarely occurs, or at least the ingrowth of bone remains restricted to the outer margins of the implant. Most sources of cadaveric bone have been freeze-dried, chemically treated, or irradiated. Unfortunately, these treatment techniques cause a severe denaturation of base proteins, increasing significantly the risk for rejection and resorption. Only in total cranial reconstruction, in which the amount of bone required far outstrips donor sources, are the advantages of cadaver bone likely to outweigh its disadvantages.

58.2.4 The Future: Craniofacial Tissue Engineering

In the pediatric population, the use of “nongrowing,” non-biological metallic and bioceramic implants have so far led to very undesirable long-term results. So, in the future, research is likely to look into the production of natural or enhanced materials that are both *osseous-inductive* and *osseous-conductive*. Efforts in tissue engineering began in earnest in the early 1990s, and owing to the worldwide incidence of congenital defects, oncologic disease, and trauma involving the craniofacial region, much work has been directed toward the biological regeneration of skin, cartilage, and bone.^{43,47,53–56} With stem cell research becoming more realistic and productive, it is hoped that all of these technologies will solve many of the problems we have today in finding biologically long-lasting repair materials for pediatric (and adult) populations.

58.3 Management of Scalp Lacerations

Scalp injuries are very commonly a concurrent injury with a skull fracture, and the neurosurgical team needs the skills to deal with both. Scalp injuries can range from simple abrasions requiring minimal care to extensive scalping injuries with total

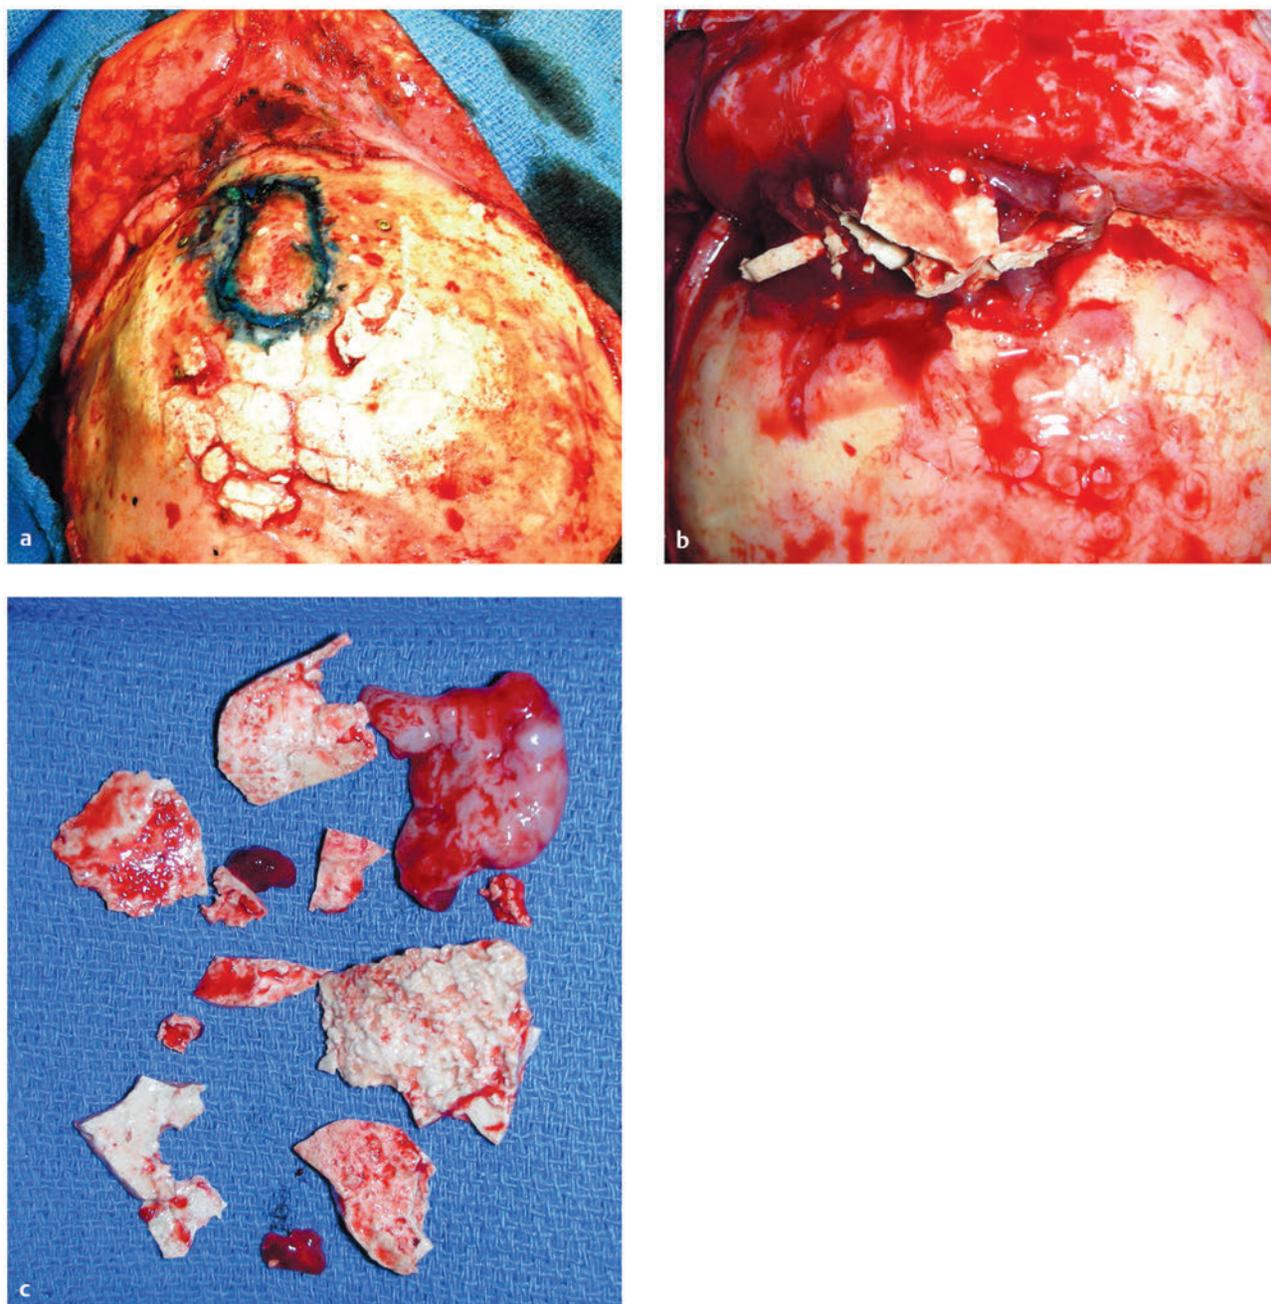

Fig. 58.17 (a) A child who as an infant had a craniectomy for metopic synostosis. The shape of the head was “normalized” with an onlay bone paste. The child presented 4 years later with a persistent pulsatile defect of the forehead. At reoperation, the bone paste was found to be only an onlay veneer that easily chipped off—there was no osseous integration. (b) A child who had a frontal region defect filled and contoured with a bone paste. The patient presented to us after mild facial trauma, with the paste fractured into pieces and totally disrupted from the defect site. (c) From a patient in whom a bone paste material had been placed to contour and smooth out several skull defects. The child presented later with the material infected and in a couple of places extruding through the skin. The paste had formed only a veneer and was easily chipped off the underlying bone.

scalp loss. Since the advent of the industrial revolution, society has become quite inventive in discovering new ways to injure the head and scalp. Each of the major types of injuries requires its own management regimen. It is the purpose of this section to review some of the surgical techniques available to the neurosurgeon (often in cooperation with our colleagues in plastic surgery) for the care and management of scalp injuries in the pediatric population.

58.3.1 Anatomy of the Scalp

An understanding of the anatomy of the scalp is a prerequisite for the repair of scalp lacerations of any type. A simple mnemonic, SCALP, still used by medical students, is helpful in recalling some of the salient points of scalp anatomy (► Fig. 58.20).

(See box “Meaning of the Mnemonic SCALP (p. 772).”)

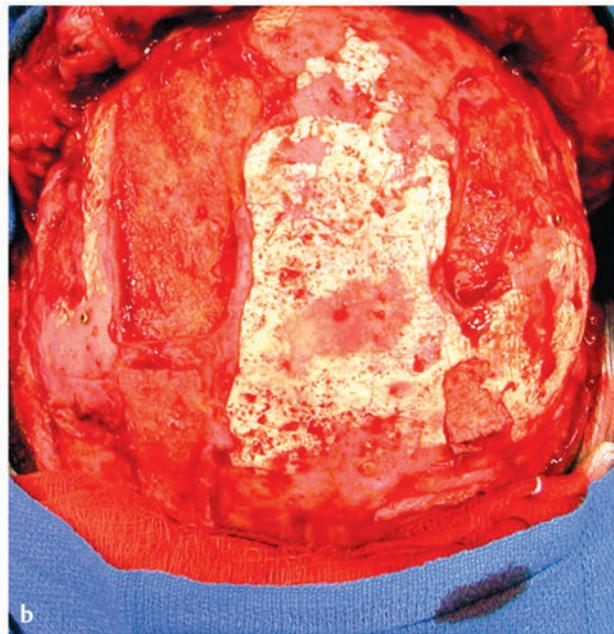

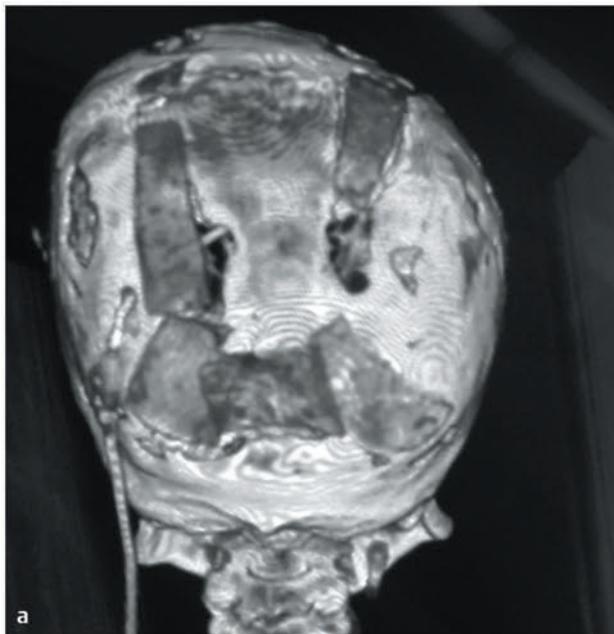

Fig. 58.18 (a) A three-dimensional computed tomographic (CT) scan of a teenager who had Proplast placed as an infant for a craniofacial reconstruction. In this CT scan, the blank areas of bone are where the Proplast was placed, and there is a clear lack of osseous integration, with large persistent bone defects still present. (b) A view of the top of skull of a patient in whom Proplast (lateral and midline placement) and bone paste were used for calvarial reconstruction. The patient presented 5 years after the bone paste had been placed for contouring with erosion of the material through the skull. As in the case shown in ► Fig. 58.16c, the bone paste easily chipped off, like a surface veneer. (c) Proplast sheets after removal and upon examination showed neither osseous conduction nor osseous integration. The material essentially acted as “onlay” graft.

Meaning of the Mnemonic SCALP

- Skin: the outer, hair-bearing portion of the scalp containing the dermis and epidermis. Aesthetically, it is the most important structure in any repair.
- Connective tissue: a thick subcutaneous layer of fat and connective tissue that attaches the skin to the underlying galea. Within this layer are nerves, arteries, and veins and the lymphatic system, all linked in a key network of anastomoses.
- Aponeurotic tissue: also called the epicranium or galeal layer. This is the fascial plane connecting the frontal and occipital muscles.

- Loose connective tissue: a layer of tissue between the aponeurotic layer and the pericranium. Its importance derives from the mobility it gives the scalp and from the fact that it is largely avascular, making it a useful plane for dissection and the elevation of scalp flaps.
- Pericranium: also called the periosteum of the skull. This layer is densely adherent to the cranial bones and contains their vascular supply. It is anatomically crucial in many of the repairs to be described. It figures importantly in repairs or reconstructions involving the face and anterior fossa and forms the foundation for skin grafts.

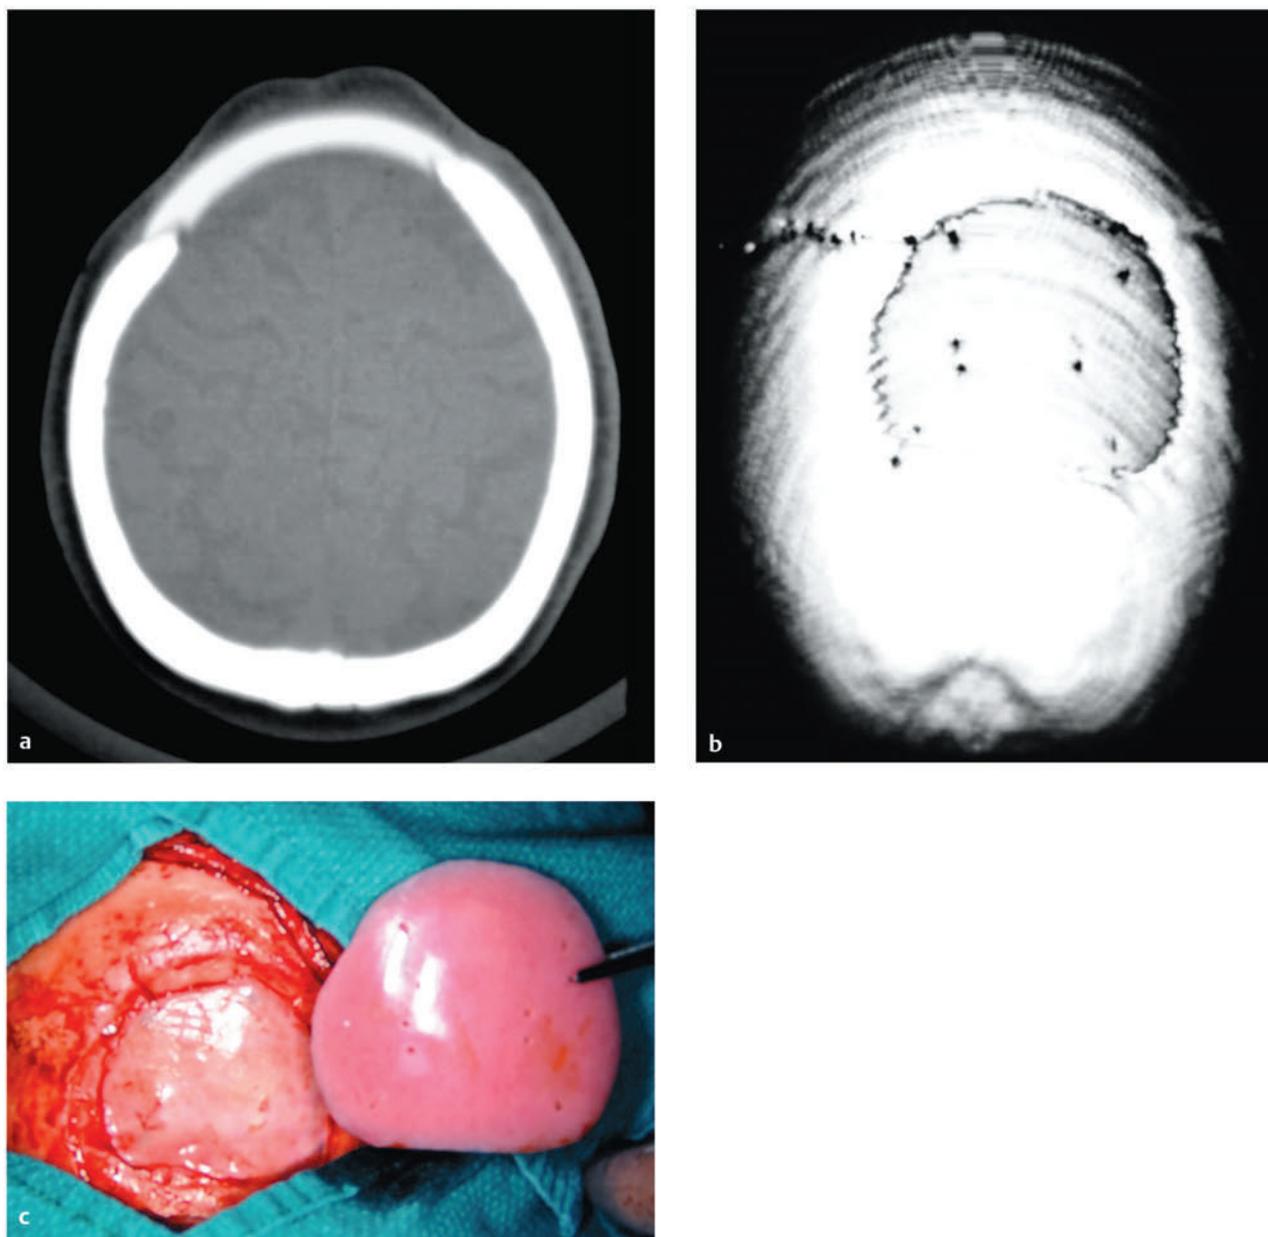

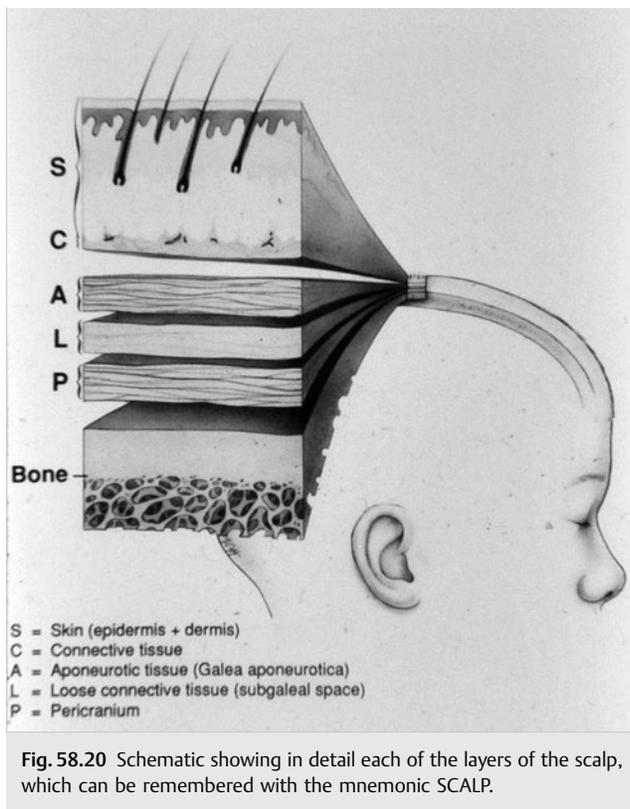

Fig. 58.19 (a) Axial computed tomography (CT) with bone windows showing a Silastic CAD/CAM (computed-aided design/computer-aided manufacturing) graft that was custom-molded for a traumatic defect. The graft shows no surrounding integration with the bone. After a blow to the patient's head 5 years following implantation, the graft became mobile. (b) Three-dimensional CT showing the Silastic implant and the clear lack of surrounding integration with the skull bone. (c) At surgery, the Silastic implant was found to "free-floating," with no attachment to the surrounding bone; there was actually loss of bone at the interface of the graft and the bone. A Silastic foreign body membrane had formed on the dural surface.

58.3.2 Vascular Anatomy of the Scalp

The scalp is essentially an end vessel in the vascular system. Twenty percent of the cardiac output is supplied to the head and neck. As a result, the bleeding associated with scalp lacerations and facial trauma can be massive and potentially lethal if not controlled. Fortunately, the scalp vascular system is a rich arcade with a large, overlapping anastomotic network. This overlapping system is so efficient that even a unilateral injury can be fed by the contralateral arterial network, leading to rapid blood loss.

The blood supply to the scalp is an extensive network, with a multiplicity of anastomoses evident. The main vessels include the superficial temporal (with two branches, frontal and parietal), the supraorbital, the frontal, the posterior auricular, and the occipital arteries. This network is anatomically constructed in a ringlike fashion at the base of the skull to supply the head and scalp. An appreciation of the general anatomy of the main trunks is key to understanding the basis of any successful flap rotation or repair of scalp lacerations.

58.3.3 General Principles

The basic principles of wound care are summarized by the mnemonic HEDSAT (see box “HEDSAT (p. 774)”).

HEDSAT

- Hemostasis
- Examination of the skull
- Débridement
- Skin closure without tension
- Antibiotics
- Tetanus prophylaxis

Because scalp injuries can hemorrhage extensively, the early control of bleeding is essential. In an emergency situation, this is readily accomplished with the application of pressure to the wound edges. Once hemostasis has been obtained, débridement and cleaning of the wound are necessary to reduce the risk for bacterial contamination (a useful rule of thumb is a bacterial count of less than 10^5 per gram of tissue). With a sterile gloved finger, the surgeon examines the skull for a defect or fracture.

Once cleaned and debrided, the wound is closed according to one of the cardinal principles of wound care: **closure without tension**. Wounds closed under tension are at high risk for breakdown, and in addition, undesirable scars will form secondary to wound separation. Techniques to reduce wound tension are discussed in a later section of this chapter.

In children up to the age of 10 years with up-to-date immunizations, the tetanus prophylaxis given with their diphtheria-pertussis-tetanus shots provides adequate protection. In older

children, past the age of 10 years, a tetanus booster will be needed if the wound is contaminated. Antibiotics are often given to children with contaminated wounds; simple, clean lacerations rarely require coverage. Potentially the most serious wounds are typically seen in the abused child afflicted with a human bite. Animal bites are often seen in emergency departments and also require aggressive treatment with antibiotics.

Most injuries encountered in the pediatric emergency department can be managed with local anesthesia. For children with extensive scalp injuries, it is more reasonable to use general anesthesia and carry out the surgical procedure in the operating room, often in collaboration with our plastic surgery colleagues.

58.3.4 Treatment of Common Scalp Injuries

Skin Abrasions

The skin abrasion is the most common injury, but it is in most instances cared for by the emergency department staff and rarely called to the attention of the neurosurgeon. If the dermis is intact and only abraded, local wound care is provided. It is most important to remove any in-driven dirt or particles that can later tattoo the skin. Occasionally, dermabrasion or coarse brushing of the dermis will be necessary; this is usually done with the patient under general anesthesia.

Skin Lacerations

Simple skin lacerations are managed by achieving hemostasis, performing routine débridement, and aligning the skin edges. Two-layer closures are rarely necessary in children except in the instance of the forehead and periorbital region, where skin sutures are removed early to reduce scarring; two-layer closure allows early suture removal. On our service, we routinely make a two-layer closure; undyed sutures are used in the subgaleal layer (dyed sutures can tattoo the very young child's skin) and fine nylon sutures (5-0 or 6-0) for skin closure; the nylon sutures are removed at 5 days. Suture placement must be meticulous and approximation of the skin edges perfect. Inadequate attention to detail makes for poor wound closure (resulting in a higher rate of infection) and disgruntled parents. Staples are inappropriate for wound closure on the face or forehead region and also inappropriate for the young child (younger than 7) because only one size—adult—is available and so provides poor skin approximation. The use of subcuticular absorbable sutures for the skin closure is desirable. Absorbable sutures do not require later removal (as would be the case with nylon material), thereby reducing further emotional trauma to the younger child.

Scalp lacerations are often accompanied by injuries to aesthetically important parts of the face and ears. In particular, it is important to line up the helical rim of the ear and the gray line of the eyelid so as to restore correct anatomical relationships; if this is done inadequately, the aesthetic outcome can be dismal. At the same time, attention must always be paid to the potential skin stretching that can distort adjacent structures. For example, in a patient with a forehead laceration that causes tissue loss, stretching the scalp to close the wound can potentially distort the face, a situation rarely acceptable to the patient or

parents. In children, as opposed to adults, there typically is less excess skin to mobilize.

In any laceration, the primary goals should always be hemostasis, débridement, and wound closure that restores the anatomical relationships as close to normal as possible.

Contaminated Scalp Lacerations

In a patient with heavily contaminated scalp lacerations, the surgical team should consider a delayed secondary closure. Bites inflicted by humans or animals and wounds contaminated with dirt (as in injuries caused by farm machinery or by motor vehicle accidents in which the child is ejected from the car) are included in this category. In these situations, it is often better to leave the wound open and apply frequent wound care for approximately 48 hours. Our team typically cleans the skin and debrided area with an antibacterial soap and Betadine paint. The goal is to achieve a bacterial contamination level that allows a primary closure (i.e., a bacterial count of $<10^5$ per gram of tissue). A swab wipe of the wound suffices to enable a bacteriology laboratory to obtain the desired organism count.

58.3.5 Treatment of Scalp Injuries with Loss of Tissue

In scalp injuries with a loss of tissue, the surgeon must keep a number of general principles in mind while mapping out the repair. (1) Aesthetic considerations always have to be taken into account in any tissue mobilization. (2) Therefore, if possible, hair-bearing scalp is mobilized and used in the repair. (3) Whenever a flap is rotated, especially a split skin graft, the rotation must be from pericranium to pericranium. (4) Preservation of the circulation in the design of the flap is critically important. Always include a major feeding vessel in any large flap rotation. (5) Caution must be exercised when electrocautery is used because heat or burn injury to hair-bearing cells can result in alopecia. Some of the newer cautery devices are now using a far-infrared radio-frequency current, which delivers much less heat and thermal injury to the wound edges.

Partial-Thickness Avulsion Loss of Scalp

Partial-thickness scalp loss can be treated in various ways. The particular technique that is chosen depends on the surface area of scalp that is lost and the extent of the injury. We review here some of the techniques that can be used by the neurosurgical team, often in collaboration with our plastic surgery colleagues.^{57,58}

Advancement Flap

In a partial avulsion of tissue with the pericranium intact, a simple technique is to elevate a flap of full-thickness scalp adjacent to the injury and then make radial cuts in the galeal layer, which will allow the scalp to be “stretched” to cover the defect. The incisions in the galeal layer are made parallel and 3 to 5 mm apart. The cuts **should not be made deep enough to**

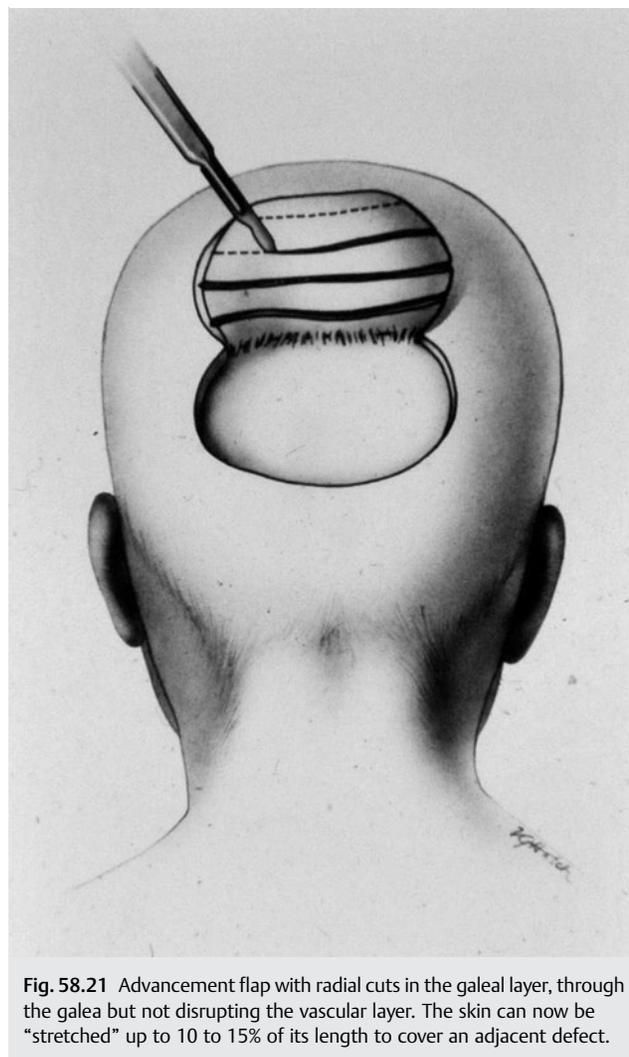

Fig. 58.21 Advancement flap with radial cuts in the galeal layer, through the galea but not disrupting the vascular layer. The skin can now be “stretched” up to 10 to 15% of its length to cover an adjacent defect.

interrupt the vascular layer; incising the galea is sufficient to obtain relaxation. Some plastic surgeons like to make cross-hatch incisions, both vertical and horizontal, and we have noted that this additional set of cuts can result in a loss of the flap due to reduced vascularity. This technique is limited by the size of the defect (usually <4 cm in the child) and the location. Furthermore, the technique cannot be used in aesthetically sensitive areas, such as the forehead, because of the potential to distort facial structures. These types of flaps are particularly useful over the high parietal and occipital region (► Fig. 58.21^{7,59}

Transposition and Rotation Flaps

The scalp injury with a small defect of less than 2 to 3 cm can be easily managed by one of the flap transposition techniques. Two relaxing incisions are made parallel to the injury in a hair-bearing region, and then the tissue is undermined with dissecting scissors by following the subgaleal plane. These parallel incisions should be no closer than 3 cm to the wound to maintain good vascularity. With wide subgaleal mobilization of

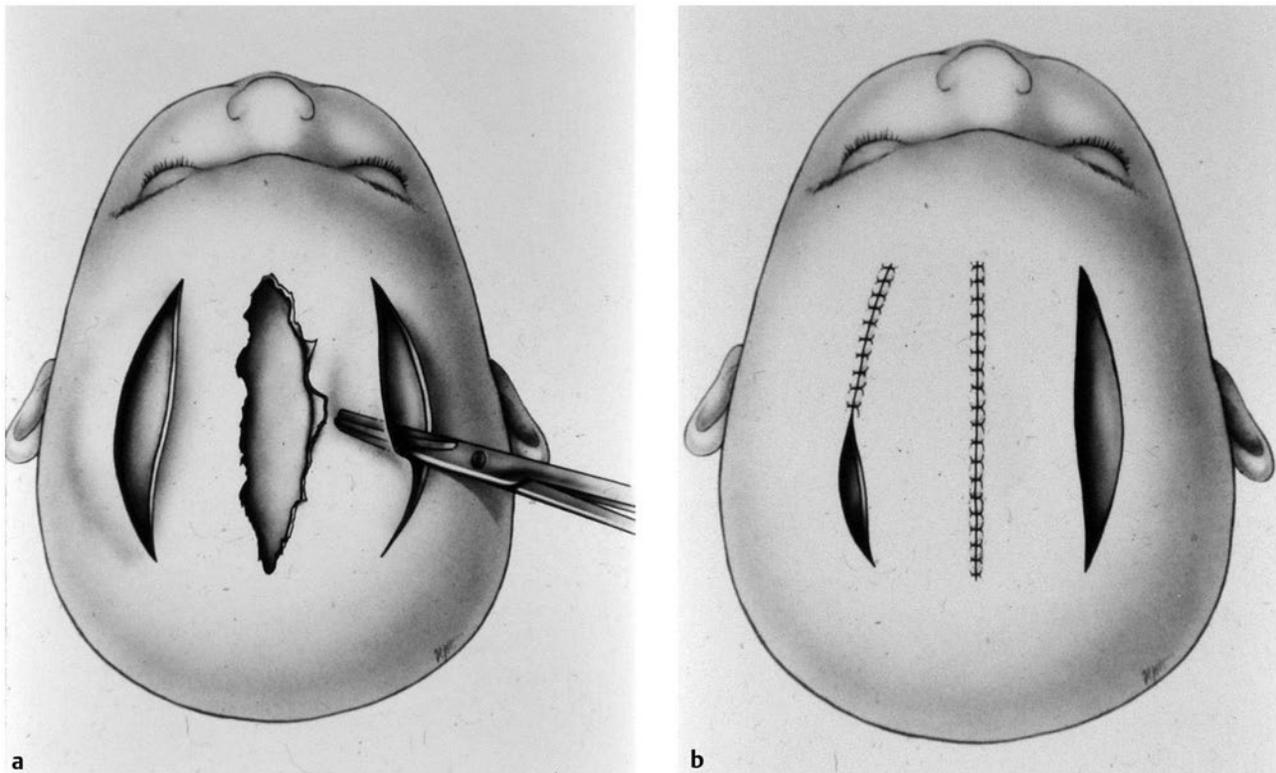

Fig. 58.22 The transposition flap, a useful technique for covering large ragged defects of the scalp. (a) With a large defect, two lateral relaxing incisions are made on each side and widely undermined. (b) The traumatic defect is closed first after the ragged wound edges have been trimmed. The lateral incisions are then further undermined to provide the necessary relaxation of tissue and skin closure with the least amount of tension possible. If the defect is so large that these maneuvers are not sufficient to reduce tension to acceptable levels, split-thickness skin grafts can always be placed in the lateral incision sites.

the skin, the initial defect is closed first primarily with as little tension as possible. The later incisions are further undermined to provide the widest degree of mobilization possible and then closed. If the extent of the transposition is too large, it may be necessary to place a split-thickness graft over the donor site to minimize tension at the wound. If such a skin graft is necessary, it can be applied over the well-vascularized pericranium, allowing a better take (► Fig. 58.22).

The Gillies tripod technique is useful in circular avulsions. The technique involves wide undermining in the subgaleal plane. The three incisions are rotated in a “tripod” fashion to the center (► Fig. 58.23).

A “lazy S-plasty” (► Fig. 58.24) is used for lateral or superiorly placed scalp defects; it is especially useful for traumatic injuries with irregular margins or in the removal of scalp lesions such as hemangiomas or neurofibromas. The flaps are elevated following a lazy S pattern; the defect is closed first, and then the suturing is extended from the center to both ends of the incision. It is not uncommon to trim the lateral margins of the transposed tissue to eliminate redundant skin and achieve an aesthetically satisfactory closure. Typically, a dog-ear is formed at the corner of the initial wound; this will mold out with time and rarely needs to be dealt with in children.

Tissue Expansion Techniques

The use of tissue expanders has revolutionized aesthetic approaches to scalp repair. A tissue expander is a silicone prosthesis that is placed into a pocket of tissue within the subgaleal space. There are a number of advantages to using this technique. With tissue expansion, one is able to develop available skin that has the same texture, color, and hair-bearing qualities as the recipient site. For aesthetic purposes, none of these qualities can be overestimated, particularly the hair-bearing qualities. Normal scalp can be expanded out to at least twice its normal interfollicular distance without showing any obvious changes in the hair-bearing areas.

The technique is straightforward and easily accomplished in the pediatric population. With the child under general anesthesia (local is not recommended in children), the prosthesis is placed in the area from which the skin flap is to be harvested. The selection of position has to be well thought out, with consideration as to whether an advancement, rotation, or transposition flap is to be undertaken. Once the prosthesis is placed into a subgaleal pocket, it is left alone for at least 3 weeks to allow the primary incision to heal well. Once healing has been accomplished, saline is injected into the prosthesis through an injection port. The prosthesis is expanded until skin tension is

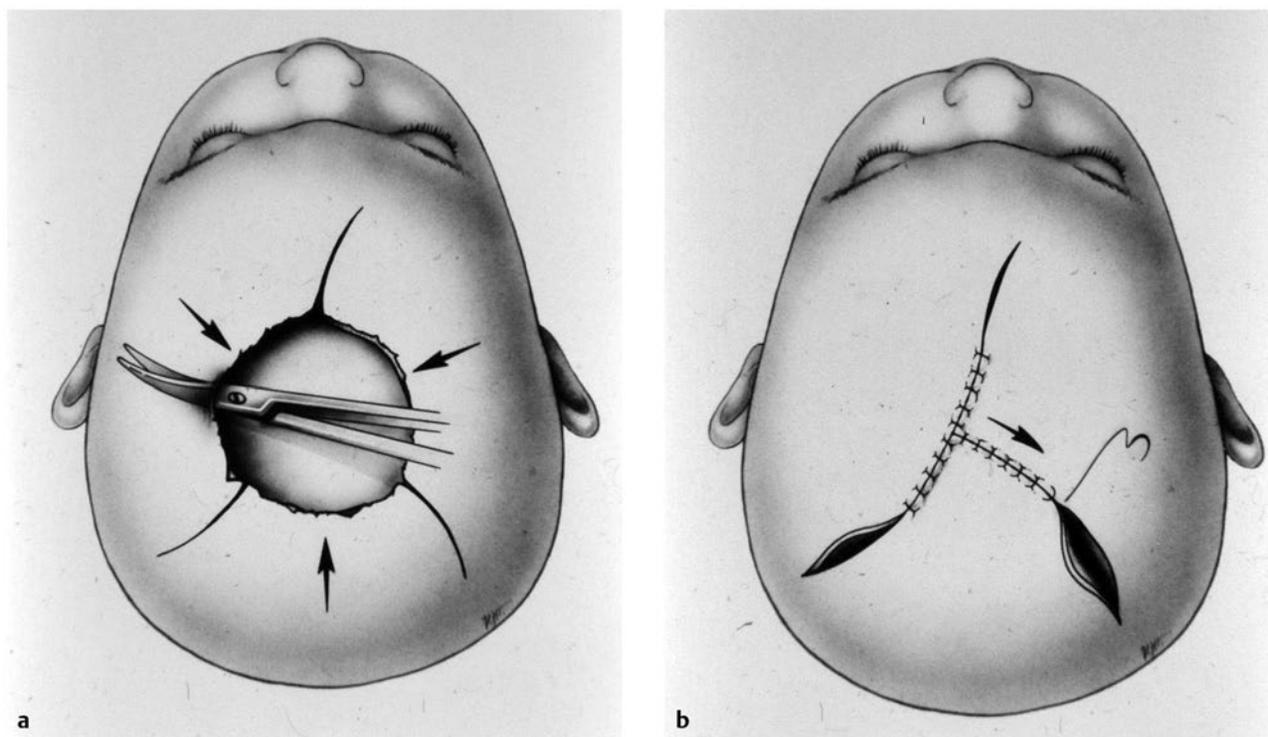

Fig. 58.23 The Gillies tripod repair, a very useful technique for closing circular defects of the high calvarial area and vertex. The arrows in (a) show the direction of the flap rotation after wide undermining of the subgaleal plane. (b) This last technique is essential for reducing tension at the wound margins.

noted. Typically, the injections are done weekly for 6 to 8 weeks, depending on the amount of redundant scalp needed. The initial 3 to 4 weeks are the most difficult for patients, especially children, but then the galea seems to relax and the expansion becomes considerably easier to accomplish. In large repairs, such as myelomeningocele flap rotations (in the older child), we have kept the prosthesis in situ for 3 to 4 months, resulting in the development of generous skin flaps. The surgeon is advised to always overexpand because typically there seems to be too little flap for the repair rather than too much. Also, at the time of expander removal, the skin, which is naturally elastic, will begin to shrink, so extra expansion is done to allow for this.

Summary for Scalp Tissue Repair

The collaboration of plastic surgeons and neurosurgeons has become a common occurrence in the operating room. As a result, the potential for the repair of complex scalp defects and complex myelomeningoceles has increased significantly. The neurosurgical team that understands the relevant anatomy and principles underlying the various rotations can perform many of these repairs. In more complex repairs, collaboration with the plastic surgeon will be beneficial. Careful attention to aesthetic considerations always makes patients and their families much happier and less socially stigmatized.

Pearls

- Autogenically harvested material (e.g., skull, rib, iliac crest) is normally the best replacement material to use in a cranioplasty. This type of material carries a lower risk for infection and will grow with the child.
- There is no contraindication to replacing open contaminated bone in a pediatric case of head trauma. As long as the bone is debrided, cleaned, and washed in a diluted Betadine (10%) solution, the replacement of this previously exposed bone does not appear to increase the risk for infection.
- In replacing bone, the use of rigid fixation helps reduce the resorption of bone and reduces the risk for slippage and displacement. The use of resorbable fixation plates in children younger than 3 years has proved very beneficial.
- For craniofacial reconstruction, the calvaria remains the best harvest site; calvarial bone carries the lowest risk for infection and the lowest risk for resorption, and the calvaria is the best area for finding appropriately contoured bone.
- It is best to minimize the use of foreign materials like bone wax and Gelfoam when bone flaps are replaced. Bone wax in particular reduces bone healing and can act as a nidus for bacteria and potential infection.

58.4 Acknowledgments

The author would like to acknowledge the wonderful cooperation over the last 27 plus years of his plastic surgery colleagues in the conceptual development of this chapter. These people

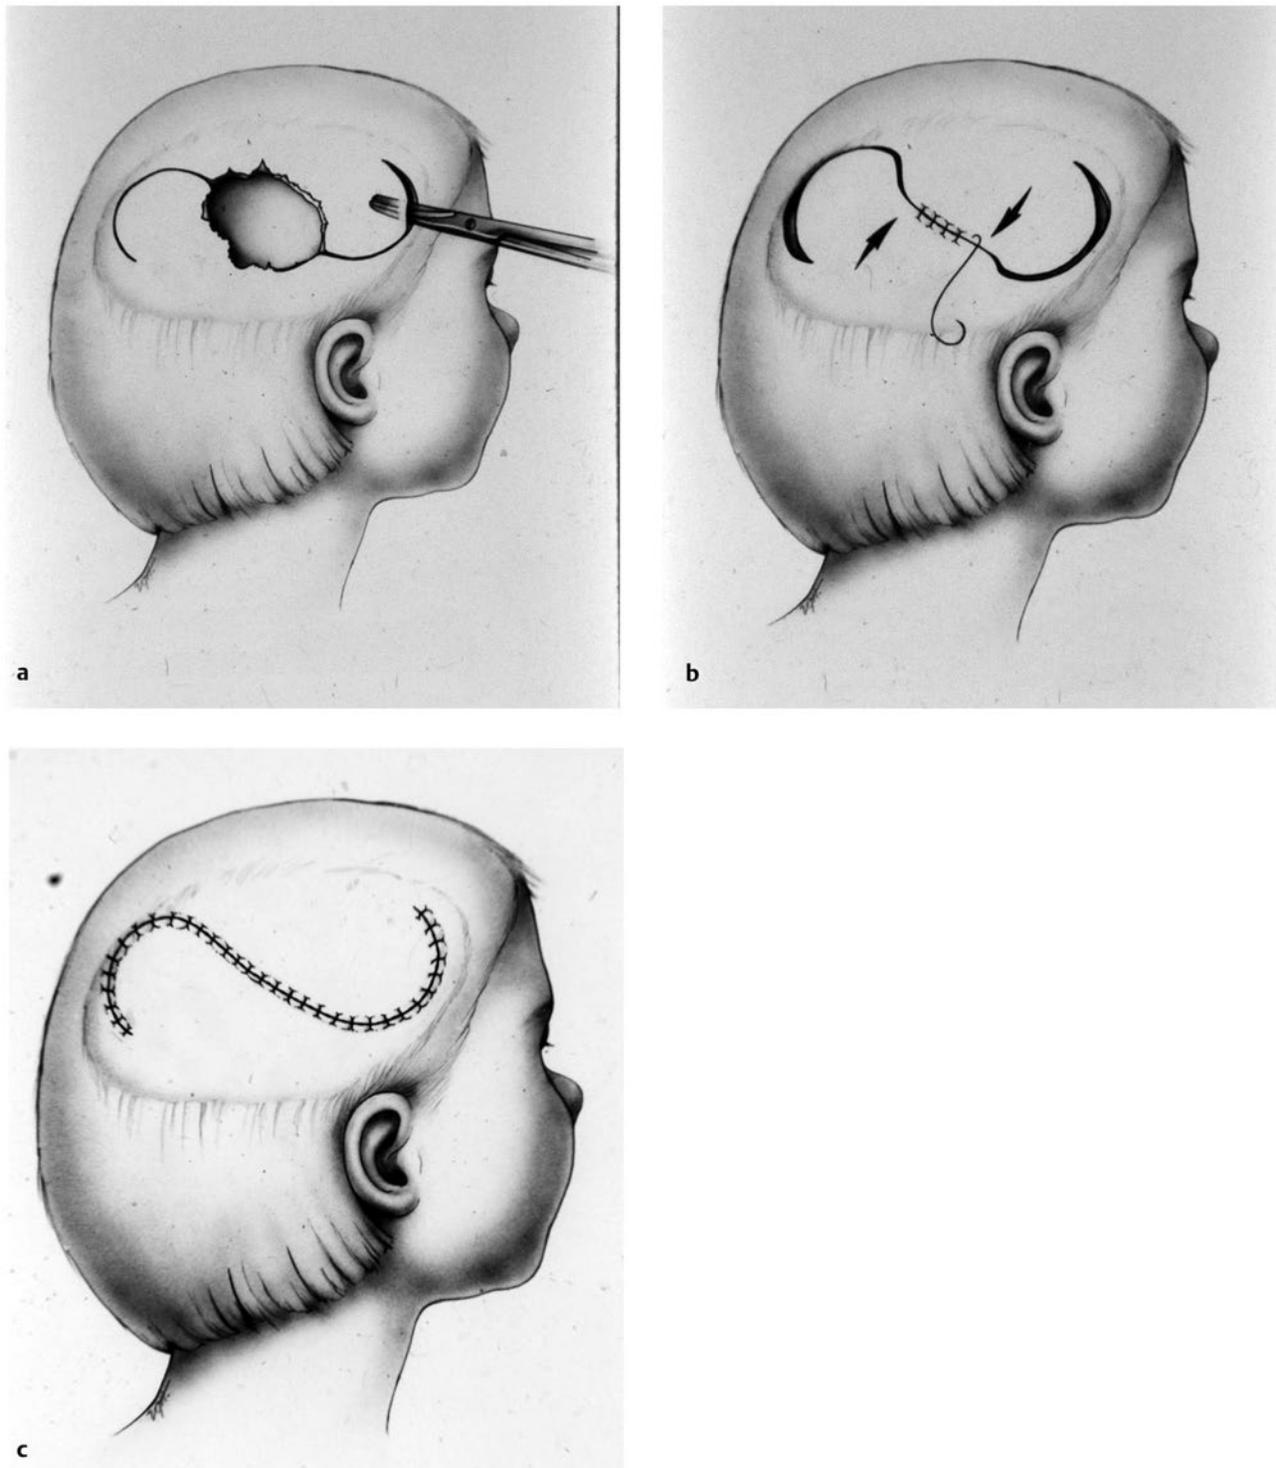

Fig. 58.24 The lazy S-plasty, a useful repair technique for larger, more irregular defects, particularly those laterally placed. (a) The curvilinear incision allows wider undermining and more flexibility in mobilizing the flaps. (b) The defect is always closed first and then the lateral margins repaired. (c) The advantage to this type of repair is the large amount of subgaleal undermining that can be done to get tissue relaxation. The lazy S incision increases the amount of skin that can be rotated.

59 Pediatric Brachial Plexus Palsy

Nathan J. Ranalli and Tae Sung Park

Pediatric obstetric brachial plexus palsy, or neonatal brachial plexus palsy (NBPP), refers to the condition arising from a traumatic insult to one or more of the cervical roots C5–C8 and T1 preceding, during, or following the birth process. Although improvements in obstetric care and heightened attention to documented risk factors for injury have resulted in reduced rates of occurrence, the incidence of NBPP has been reported to be between 0.38 and 5.8 per 1,000 live births; an extensive epidemiologic review by Foad et al in 2008 demonstrated an incidence of 1.51 cases per 1,000 live births in the United States.^{1–3} For many children, the deficits are mild and transient, with rates of spontaneous recovery between 75 and 95% cited in the literature.^{4–7} More recent reports, however, have suggested that these outcomes may be overly optimistic, finding much lower recovery rates and significant permanent disabilities in affected patients who were managed conservatively.^{4,8–14}

In the past several decades, it has become increasingly apparent that the role of the pediatric neurosurgeon in the management of NBPP centers on the proper selection of patients for whom surgical intervention will be of benefit. This chapter reviews the anatomy and pathophysiology of NBPP, discusses the clinical presentation and comprehensive evaluation of these patients, and illustrates the current approach to the operative treatment of NBPP; the focus is on surgical timing, microsurgical techniques, treatment adjuncts, prognosis, and secondary reconstruction.

59.1 History

Although the first clinical description of birth-related brachial plexus injury was made by William Smellie in 1764, the term *obstetric palsy* was not coined until 1872. Guillaume Duchenne detailed four cases of upper brachial plexus palsy due to excessive traction on the arm and shoulder during birth, with resultant root avulsions.^{15,16} Two years later, Wilhelm Erb identified the site at which the C5 and C6 nerve roots join in the neck as the location of injury in patients with weakness of the deltoid, biceps, coracobrachialis, and brachioradialis muscles; therefore, the term *Erb* (or *Erb-Duchenne*) *palsy* refers to the classic upper brachial plexus injury involving only the upper trunk of C5 and C6 with or without C7.¹⁷ A century later, Augusta Klumpke illustrated the relationship between the Horner sign and T1 root avulsion in brachial plexus lesions; the term *Klumpke palsy*, the least common pattern of injury in NBPP, refers to an insult isolated to the lower trunk of the C8 and T1 roots.¹⁸

The first report of surgical treatment for NBPP came from Robert Kennedy in his 1903 publication describing the neurotomy resection and neurorrhaphy of the injured fifth and sixth cervical roots in a young boy with Erb palsy, and the positive results were documented pictorially.¹⁹ A subsequent review of 1,100 cases of obstetric brachial plexus palsies by Sever in 1925 concluded, however, that patients managed conservatively or surgically had the same outcomes.²⁰ In light of this finding, primary operative intervention for NBPP was rarely employed until the advent of microsurgical techniques and improved

pediatric anesthesia in the 1970s. The published works of Millei, Narakas, and Gilbert et al, each highlighting favorable results in patients with NBPP treated with direct surgical repair, rekindled an interest in the operative treatment of birth brachial plexus palsy that continues to this day.^{21–23}

59.2 Epidemiology

At present, NBPP occurs in more than 5,400 children born in the United States each year, and rates are nearly equal between male and female newborns.^{24,25} Although some authors have cited congenital malformations and uterine cavity abnormalities as possible causes of obstetric brachial plexus palsy, the presumed etiology of NBPP is difficult childbirth and the excessive application of lateral traction forces to the nerves during delivery.^{26–28} This scenario usually occurs in the setting of shoulder dystocia, in which the upper extremity is pulled in excess of nerve tolerance during extrication, or of hyperextension of the arms in a breech delivery.²⁹ Trauma to the upper roots of the plexus typically takes place in a vertex delivery with shoulder dystocia when the neck is laterally flexed with the arm in adduction to free the shoulder from the pubic arch. Because of the more common left occiput anterior presentation of the descending fetus, right-sided lesions occur more frequently; injury to the posterior shoulder, however, may occur when that shoulder is lodged on the maternal sacral promontory during the birthing process.^{26,30} Bilateral injuries have been reported with breech presentation, although unilateral insults to the upper roots are still seen more often in that setting.^{31,32} Several investigations have demonstrated that more than 1% of cases of NBPP occur following cesarean deliveries.^{33,34}

59.3 Risk Factors

Despite increased awareness of the problem, NBPP is not a preventable disease. In fact, a study by Mollberg et al showed that the incidence of obstetric palsy has actually increased in one industrialized country over a recent 10-year period.³⁵ As a result, significant attention has been paid to the identification of predisposing factors that may be associated with the occurrence of NBPP. These include maternal characteristics, such as obesity and excessive maternal weight gain, primiparity, grand multiparity, gestational diabetes, and advanced maternal age (older than 35 years); labor-related factors are shoulder dystocia, prolonged second stage of labor, vaginal breech delivery, instrument (vacuum)-assisted vaginal delivery, and epidural analgesia. The most important fetal trait is macrosomia (birth weight > 4,500 g).^{36–40} Several recent studies have determined that shoulder dystocia and the ancillary maneuvers required to deliver the shoulders are the most prevalent risk factor for NBPP, although prior reports suggested it is much less common.^{41–43} The observation that some patients with NBPP have one or more risk factors while others have none has led some investigators to hypothesize that not all permanent brachial plexus injury is due to birth-related traction, and some patients may

have an undefined or inherent susceptibility to the condition.⁴⁴⁻⁴⁶ Other traumatic lesions, such as fractures of the clavicle and humerus, facial nerve injury, cephalohematoma, and torticollis, have been associated with obstetric brachial plexus palsy.^{41,47-50}

59.4 Surgical Anatomy and Pathophysiology

Peripheral nerve injuries have been classically described and categorized, first by Seddon in 1943 and later by Sunderland in 1951.^{51,52} In Seddon's classification (and Sunderland I), neurapraxia refers to a physiologic block of nerve conduction within affected axons without a loss of axonal continuity; it is the mildest form of injury, and full recovery is generally observed in days to weeks. Axonotmesis (Sunderland II-IV) involves a relative loss of continuity of the axon and its myelin sheath, but with preservation of the epineurium and perineurium; wallerian degeneration and scar formation occur, but recovery may take place without surgical intervention if the axons successfully grow back to reach the target muscle. Neurotmesis (Sunderland V) describes a total severance or disruption of the entire nerve fiber; recovery from this injury is not possible without timely surgical treatment. Mechanically, these insults have been referred to as stretch (Sunderland I), varying degrees of rupture (Sunderland II-V), and avulsions.⁵³

More clinically relevant than pathologic severity is the anatomical localization of the brachial plexus injury. Most authors recognize four major patterns of injury, described by Narakas and others, involving three plexus palsy categories: upper, lower, and total.⁵⁴⁻⁵⁶ The first and most common is a purely upper brachial plexus lesion affecting C5 and C6 (Erb palsy) and causing weakness of only the deltoid and biceps; several reports have demonstrated evidence of rates of spontaneous recovery as high as 90% in these cases.^{57,58} The second presentation is that of an injury involving the C5, C6, and C7 roots. The arm is internally rotated and adducted at the shoulder, the elbow is extended, the forearm is pronated, and the wrist is flexed with fingers extended, resulting in the "waiter's tip" posture. The next most common type of birth palsy, accounting for 9 to 26% of cases of NBPP, is that of a total brachial plexus injury involving the C5-T1 roots; it is the most devastating injury to the brachial plexus with the least favorable outcomes.^{4,26,59,60} These newborns manifest flaccid, insensate paralysis of the entire arm and hand with pale or mottled skin due to vasomotor impairment; Horner syndrome (ptosis, myosis, enophthalmos, and anhydrosis) may or may not be seen. The final and exceedingly rare pattern of injury is that of Klumpke palsy, due to damage of the lower roots C8 and T1. The clinical features include a "claw hand" posture and Horner syndrome and are seen in fewer than 1% of obstetric palsies.⁵⁷

Neonatal injuries of the brachial plexus may be further subcategorized as supraclavicular, affecting the roots and/or trunks, or infraclavicular, involving plexus lesions distal to the level of the cords. The determination of the pre- or postganglionic nature of the level of injury is important for prognostic purposes.^{61,62} Preganglionic lesions are avulsions from the spinal cord that cause denervation weakness in all muscles supplied

by the injured root (motor cell bodies in the spinal cord), but nerve conduction (sensory cell bodies in the dorsal root ganglion) is intact. Damage to the nerves arising in proximity to the ganglion, including the phrenic (elevated hemidiaphragm), long thoracic (winged scapula), dorsal scapular (absence of rhomboid), suprascapular (rotator cuff), and thoracodorsal (latissimus dorsi) nerves, or the presence of Horner syndrome (preganglionic sympathetic fibers to the eye join the sympathetic chain from the T1 spinal nerve) resulting in mydriasis and ptosis suggests a significant preganglionic injury.⁶³ These cases do not recover motor function spontaneously. Postganglionic ruptures generally result in sensory conduction delay and the paralysis of target muscles innervated by the trunk level and beyond; such lesions have sufficient proximal and distal nerve components relative to the site of injury to be amenable to surgical repair and reconstruction.⁶⁴ A common pattern of injury is postganglionic rupture of the roots and trunks in the supraclavicular compartment (Erb palsy) and preganglionic avulsion in the infraclavicular compartment.^{59,65}

59.5 Natural History and Recovery Potential

As noted in the introduction, previous reports have documented that the majority of patients with NBPP have an overall favorable prognosis, showing that 70 to 95% had a complete spontaneous recovery with conservative management (physical therapy).^{6,55,66-68} Gordon et al found that 90% of patients showed improvement by 4 months of age, and Greenwald and others reported recovery within the first 3 months in 92% of patients.^{4,69} More recently, however, Hoeksma et al published a complete neurologic recovery rate of only 66% in a series of 56 patients, and Bager found severe impairment in 22% of 52 Swedish children with NBPP.^{8,70} We found at our own institution that 66% of 80 infants with NBPP achieved complete recovery, defined as antigravity movement in the biceps, triceps, and deltoid muscles by 4.5 months of age.⁹ In the cases of complete recovery, all patients achieved three-fifths strength in all three muscle groups by 5.5 months at the latest, and any permanent weakness was apparent by 6 months of age as two-fifths or lower strength in the biceps, triceps, or deltoid muscle. Narakas determined that satisfactory recovery in patients with total palsy was extremely unusual, and Al-Qattan et al found that none of 22 patients with Horner syndrome in their series achieved a positive outcome.^{54,71} Factors that portend a worse prognosis include total plexopathy and lower plexus injury, Horner syndrome, and multiple root avulsions.^{6,26,59,72} A systematic review by Pondaag et al in 2004 concluded that the most commonly reported high recovery rates were based on inadequate study methodologies limited by insufficient follow-up periods, unclear criteria for permanent injury, and lack of a final evaluation by a brachial plexus specialist.¹⁰ An evidence-based review focusing on prognosis following NBPP by Foad et al, published in 2009, reported that of 11 studies from 1966 through 2006 that met criteria for inclusion, only four achieved an Oxford evidence-based grading scale level of 1 or 2; they concluded that the quality of the literature on this subject is poor and that the rates of spontaneous recovery are significantly lower than those documented in early reports (even among

patients with upper trunk palsies, only 64% had a spontaneous recovery of biceps function at 3 months).⁷³

Despite the discordant data, several points remain clear. Most cases of NBPP are transient and show some improvement beginning as early as 2 weeks of age with supervised home therapy to support passive range of motion.⁷⁴ Infants who achieve partial antigravity strength in upper trunk-innervated muscles within the first 2 months are likely to progress to complete recovery over the next 2 years, whereas those who do not recover antigravity strength by 5 to 6 months after birth are unlikely to recover completely without surgical intervention.⁷⁵ Global shoulder function is increasingly impaired with longer duration of biceps muscle recovery, and these patients are likely to experience permanent, debilitating limitations of motion and strength as well as joint contractures.⁷⁶ Infants who demonstrate no signs of recovery and have a persistently flaccid arm at 2 months of age have a total palsy with an unfavorable long-term prognosis.^{26,41,67,77}

59.6 Patient Evaluation

59.6.1 Neurologic Examination

At our institution, patients in whom NBPP is diagnosed are evaluated as soon as possible after birth in a comprehensive multidisciplinary brachial plexus clinic comprised of a pediatric neurosurgeon, a pediatric neurologist, an orthopedic surgeon, physical and occupational therapists, a neuroradiologist, an electrophysiologist, and a nurse coordinator. A complete examination is performed, with the focus on a detailed obstetric and birth history, with the presence or absence of the aforementioned risk factors for NBPP noted. A careful assessment of passive range of motion of the involved arm, forearm, hand, and shoulder is made, often by simply observing spontaneous activity and coaxing the patient to reach for items with and without assistance. Numerous scales exist for evaluating motor strength, including the British Medical Research Council muscle movement scale, the Gilbert and Tassin muscle grading system, the Mallet scale, and the Hospital for Sick Children (Toronto) muscle grading system.^{78–81} We use the modified and simplified Medical Research Council scale (MRC 0–5) for all infants and, for patients older than 2 years who are able to cooperate, the Mallet scale in order to document functional changes in the shoulder and arm. In newborns, the presence or absence of a pinch response may provide useful information regarding sensory loss; evidence of self-mutilation of the fingers may be appreciated as well. Narakas classified the sensory responses of infants with NBPP into four groups.⁵⁴ Suspected associated injuries like rib, spine, clavicle, or humerus fractures or observed asymmetry of chest wall expansion should be clarified with inspiratory and expiratory plain radiographs. Fractures of the humerus and clavicle, the bones most commonly broken during delivery, can cause compression of the brachial plexus and a pseudoparalysis that mimics true NBPP.^{78,82,83} Other entities in

the differential diagnosis include congenital aplasia of brachial plexus nerve roots, congenital Varicella of the upper extremity, umbilical cord palsy, and intrauterine maladaptation palsy.

Typically, the inflammatory component of the birth trauma resolves over several days or weeks, and the true nature of the child's injury becomes more apparent. Many patients with palsies recover completely in this time frame, signifying a neurapraxic insult, whereas others improve from an entirely flaccid arm to a purely upper plexus palsy. Physical therapy in the form of passive range of motion exercises is initiated at home within the first month, and the patient returns to the clinic 4 weeks after birth. If the child still has a total palsy, particularly in the presence of Horner syndrome, the poor prognosis is explained to the parents and surgical intervention is discussed; numerous publications support microsurgical reconstruction in these infants by 3 months of age.^{59,64,79,84} If the patient exhibits evidence of improving hand function without shoulder or biceps recovery, physical therapy is continued, and he or she is seen on a monthly basis.⁸⁵ By 3 to 4 months of age, infants with antigravity strength or greater in the biceps, triceps, or deltoid muscle may be followed expectantly; children with less than antigravity strength in each of these muscles undergo neuroimaging and electrophysiologic studies in preparation for likely surgical intervention.⁹ If at 6 months of age the aforementioned muscles still have not recovered antigravity strength, brachial plexus exploration and repair are recommended. This practice pattern is based on our own prospective study of conservatively managed patients, in which we found that antigravity muscle strength at 3 months is prognostic for progression to a full recovery without an operation; similar strength testing at 6 months identifies those patients with less than antigravity strength who will not achieve a satisfactory outcome (antigravity strength) without surgery.⁸⁶ We believe this approach minimizes unnecessary surgical intervention in children destined to recover spontaneously yet avoids the development of irreversible joint contractures or permanent muscle atrophy in those patients who will ultimately benefit from microsurgical repair.

59.6.2 Other Tests

Ancillary studies often used in the evaluation of a patient with NBPP include plain radiography, electromyography (EMG) and nerve conduction studies, magnetic resonance (MR) imaging, and computed tomographic (CT) myelography. As mentioned, when phrenic nerve injury is a concern on examination, chest X-rays should be obtained to look for an elevated hemidiaphragm; when fractures of the ribs, clavicle, spine, or humerus are present, radiographs of the specific site of suspected injury should be obtained.

If a patient presents with NBPP without evidence of obstetric trauma and an intrauterine injury is considered, EMG is performed within a week of delivery to assess for denervation and to clarify the timing of the event.^{87,88} When surgical interven-

tion is proposed, EMG and nerve conduction studies are undertaken in some centers 3 months after birth. Details regarding the extent and distribution of the brachial plexus injury, as well as the expected pattern of recovery, may be collected; additionally, evidence of normal sensory conduction in the setting of severe motor weakness suggests a nerve root avulsion or preganglionic injury. Although EMG is standard in the work-up of adult brachial plexus injuries, its utility in the evaluation of NBPP is not as clear. Several studies have suggested that because denervation disappears early in newborn trauma and extensive collateral sprouting occurs rapidly to affected muscles, EMG may not accurately portray the severity of the clinical condition.⁸⁹ We have not found EMG to be particularly helpful in our own practice.

When the decision is made to proceed with brachial plexus exploration, we use T1- and T2-weighted fast spin-echo cervical MR imaging sequences to look for pseudomeningoceles as a marker for nerve root avulsion, as well as any sign of spinal cord injury.^{90,91} It is worth noting, however, that 15% of pseudomeningoceles are not associated with complete nerve root avulsion, and 20% of surgically diagnosed avulsed roots may not be associated with a pseudomeningocele.^{49,92} A retrospective review by Smith et al in 2008 demonstrated in a small group of infants with birth-related brachial plexus injuries the ability of MR neurography to aid in the anatomical localization and characterization of nerve swelling, neuromas, and denervation changes.⁹³ CT myelography is an invasive alternative to MR imaging that provides a better delineation of the nerve roots and intervertebral foramina but requires general anesthesia, lumbar puncture, intrathecal contrast, and exposure to radiation.

59.7 Timing of Surgery

The primary clinical dilemma is to determine if an infant with NBPP warrants surgical exploration and reconstruction, and the absence of motor recovery is the main indication for operative intervention. Because these patients have varying degrees of nerve pathology (Sunderland II through IV) and their neuromuscular recovery following conservative management versus that after microsurgical intervention have not yet been compared in a prospective or randomized controlled manner, the timing of surgical treatment remains controversial.⁹⁴ As early as 1917, Wyeth and Sharpe advocated surgery if there were no signs of motor recovery 3 months after birth.⁷⁷ Many authors cite Gilbert and Tassin's classic study of 44 children with NBPP in whom recovery of the biceps muscle at 3 months of age served as the indicator for expected spontaneous recovery (shoulder function was better in infants who showed biceps and deltoid recovery before 3 months) and recommend surgical exploration at 3 months if sufficient improvement has not occurred.⁸⁰ Laurent et al espoused close monitoring of the triceps and deltoid muscles, in addition to the biceps, to determine microsurgical intervention.⁵⁹ Chuang et al proposed that an aggressive approach (exploration at 3 months) is indicated for total palsy but only relatively so for lesions of the upper plexus.⁹⁵ We found in our own series that patients who continued with

less than antigravity biceps strength by 6 months of age had unsatisfactory outcomes with nonsurgical management.⁹ Terzis and Papakonstantinou argued for operative intervention at 4 to 6 weeks in patients with severe global injuries and at 3 months in children with isolated C5–C6 deficits and absence of antigravity biceps or deltoid recovery.²⁵ Clarke and Curtis, on the other hand, recommended employing the “cookie test” to evaluate isolated elbow flexion recovery at 9 months of age as a measure of prognosis and to guide surgical treatment.⁷⁸

59.8 Surgical Treatment

59.8.1 Anesthesia and Exposure

Before the operation, we make a concerted effort to counsel the parents regarding expectations and emphasize that the goal of surgery is to improve the functional capabilities of the arm, that it may never be completely normal, and that recognizable benefits may not appear for up to 6 months.

Surgery is performed under general anesthesia with a short-acting neuromuscular agent to permit intraoperative electrical stimulation.³⁰ Following induction, the patient is positioned supine with a gel shoulder roll placed to elevate the clavicular region, and the head is rotated contralaterally. The entire neck, chest, and affected upper extremity and both lower limbs are prepared in a sterile manner to allow visual inspection of the muscles of the affected arm during surgery and to accommodate the potential need for bilateral sural nerve graft harvesting; this last point has been modified recently at our own institution as we have started using a peripheral nerve allograft in lieu of sural nerve autografts (Avance; AxoGen, Alachua, FL) in order to spare the patient a second (or third) surgical site. For an Erb or upper trunk palsy, a standard supraclavicular approach is used, whereas treatment of the lower plexus requires an infraclavicular exposure. The incision for the former begins two fingerbreadths beneath the mastoid tip and follows the posterior border of the sternocleidomastoid muscle to the midpoint of the clavicle; if a combined approach is indicated, the incision is extended laterally along the superior border of the clavicle to the deltopectoral groove and curved inferiorly to the anterior axillary fold. The entire operation is done under microscopic visualization.

Once the incision is made through the skin and platysma muscle for the supraclavicular approach, the flaps are raised, and a layer of fibrofatty tissue overlying the brachial plexus posterior to the sternocleidomastoid muscle is elevated with sharp dissection. The omohyoid muscle is divided, and the transverse cervical vessels are retracted or cauterized. Dissection continues down to the clavicle, with subsequent division of the subclavius muscle and clavicular periosteum. Although some authors routinely perform a clavicular osteotomy to improve exposure for combined approaches, others connect the supra- and infraclavicular plexus elements through subclavicular blunt dissection; if necessary, the clavicular portion of the pectoralis major muscle may be dissected from the clavicle, with preservation of the pectoral nerve, in order to expose the cords of the brachial plexus.⁹⁶

The first goal is to reveal the C5 and C6 nerve roots and upper trunk, which requires identification of both the phrenic nerve along the anterior scalene muscle and the spinal accessory nerve arising from the C4 root; the latter may be seen at the posterior junction of the upper and middle thirds of the sternocleidomastoid muscle. Direct electrical stimulation and observation of responses are used throughout the dissection and aid in the labeling of these nerves. The upper trunk neuroma is likely to be readily apparent, and the C5 root is identified by tracing the most superficial portion of the upper trunk toward the neural foramen. The anterior scalene muscle is then divided and partially resected to provide access to the C6–T1 nerve roots; care must be taken when the T1 root is exposed, given its proximity to the pleura and subclavian vessels. Soft Silastic (Dow Corning, Midland, MI) vessel loops are used to designate and retract the roots, while the three trunks are identified close to the clavicle and freed from surrounding fibrotic tissue. The dorsal scapular and suprascapular nerves will be located arising from the C5 root and upper trunk, respectively; the long thoracic nerve will often be found under the upper trunk above the middle scalene muscle. Infraclavicular exposure is achieved by dissecting along the deltopectoral groove, with subsequent division of the pectoralis major at its insertion into the humerus and at the midpoint of the pectoralis minor; the cephalic vein is preserved, and marking sutures are used in the pectoralis major to facilitate closure. At this point, the cords of the brachial plexus as well as the median, ulnar, musculocutaneous, and axillary nerves may be identified.

Traditionally, we have harvested autologous sural nerve grafts through bilateral open posterior lower leg stepladder incisions; endoscopic harvest of the sural nerves has also been described.⁹⁷ Because the sensory sural nerves are smaller than the mixed nerves of the brachial plexus, multiple segments of sural nerve are needed following neuroma resection to create an adequate graft spanning the distance from nerve root to trunk. This requires a second or third incision, increases the risk for wound infection, and may cause postoperative pain or paresthesias. Recently, we have instead used a decellularized and sterile extracellular matrix processed from donor human peripheral nerve tissue called Avance. Alternative donor sites include nerves in areas of the patient's own plexus where reinnervation is unlikely to occur, including the medial cutaneous nerve of the forearm.

59.8.2 Resection of Neuromas

Surgical options for the treatment of neonatal brachial plexus palsy include neurolysis, complete or partial resection of the neuroma, and repair by nerve grafting with or without intra- and/or extra-plexus nerve transfers.⁹⁸ External neurolysis alone is employed only when the neural elements show evidence of mild traction injury without disruption of the perineurial sheath; the resection of conducting neuromas in continuity has been shown to have better results than neurolysis alone.⁹⁹ Nevertheless, controversy exists regarding the optimal intraoperative management of neuromas, particularly in light of the fact that the use of nerve action potential measurements during surgery as a prognostic tool has not been validated in the pedia-

tric population.^{100,101} Some authors resect all neuromas unless distinct fascicular architecture is observed.^{26,29,41,67} Laurent and colleagues depend on the intraoperative assessment of compound muscle action potentials (CMAPs) across a neuroma to determine whether to perform neurolysis or neuroma resection and nerve grafting; a drop in the CMAP of more than 50% indicates resection, and a drop of less than 50% results in neurolysis.^{58,59,102} We combine a semiquantitative evaluation of muscle contraction in response to electrical stimulation of the nerve root proximal to the neuroma with intraoperative inspection of the neuroma, awareness of the preoperative muscle strength, and knowledge of the MR imaging findings to arrive at a decision. Generally, if the root or trunk is ruptured and electrical stimulation of up to 10 milliamperes generates no or minimal muscle contraction, the neuroma is resected. If there is evidence of nerve root avulsion and weak conduction through the remaining nerve root, then the nerve root sheath is divided. If the brachial plexus is in continuity but elicited muscle contraction is poor, the neuroma is resected. If the brachial plexus is in continuity and strong muscle contraction is observed following electrical stimulation of the proximal nerve root and the neuromas are not extensive, no resection is undertaken.

59.8.3 Repair Procedures

The primary objective of surgery for Erb or upper trunk palsy is to restore shoulder and biceps muscle function through a variety of grafting and neurotization procedures. These include using the stumps of the C5 and/or C6 roots, the C7 nerve root, or the spinal accessory nerve for grafting to all or part of the upper trunk, suprascapular nerve, and axillary nerve arising from the posterior cord. For total plexus injury, multiple nerve grafts must be employed. If several nerve root stumps are identified, these are divided and used for grafting all trunks and cords of the brachial plexus. If only a single nerve root stump is accessible, it is grafted to the musculocutaneous nerve. All nerve grafts should be prepared 10 to 15% longer than the measured defect length and combined to match the diameter of the host nerves. Neuroorrhaphy is performed with 9–0 Prolene (Ethicon, Somerville, NJ) epineurial sutures combined with fibrin glue.

Nerve root avulsions require neurotization. Historically, this has meant nerve crossover or transfer between an uninjured neighboring donor nerve and a distal segment of a nonfunctioning nerve directly or with grafts. Nerve transfers involve motor-to-motor neural connections and may be used primarily or in late cases to augment function in the setting of partial neurologic recovery.⁶³ Spinal accessory, phrenic, intercostal, medial pectoral, thoracodorsal, long thoracic, and subscapular nerves have all been used for neurotization. When a transfer of the spinal accessory nerve to the suprascapular nerve is used to reinnervate the infra- and suprascapular muscles, care must be taken to section the nerve distal to the first branch to the trapezius muscle in order to avoid a significant motor deficit.^{22,103} This can be combined with a transfer of the long head of the triceps motor branch of the radial nerve to the anterior portion of the axillary nerve for improved shoulder abduction.^{10,104–106} Al-Qattan and others have employed the technique described by Oberlin et al for transferring the fascicles of the ulnar nerve that

supply the flexor carpi ulnaris to the motor branches of the biceps in patients with good recovery of shoulder function but little or no elbow flexion; more recently, transfer of the motor fibers of the median nerve and medial pectoral nerve has also been described in such children with good success.¹⁰⁷⁻¹¹¹ We perform the transfer only in the setting of a secondary operation, either when the primary neurolysis/grafting did not result in adequate biceps function (as above) or when the primary exploration revealed such severely traumatized roots/trunks that grafting was impossible (one patient who returned at a later date for multiple transfers). We do think, however, that the Oberlin transfer could be considered at the primary operation for a patient who achieved spontaneous recovery of shoulder function without satisfactory recovery of biceps function by the 6-month time point. The phrenic nerve transfer has also proved safe and effective in adults with normal diaphragmatic function but is not recommended in infants in light of their immature respiratory system and greater risk for fatal pulmonary complications. Additionally, the long-term efficacy of neurotization with the long thoracic, thoracodorsal, subscapular, and pectoral nerves in babies is unknown.

Wound closure is performed in layers, including reinsertion of the pectoralis major muscle (if sectioned) and the platysma muscle, in a routine manner. The shoulder is maintained in adduction over the trunk with an elastic bandage and sling, and a soft collar is applied to the neck.

59.8.4 Complications

Risks of the surgery include loss of preoperative muscle strength, injury to the phrenic nerve with diaphragmatic paralysis, cerebrospinal fluid leak, pneumothorax, thoracic duct injury (left-sided approach only), injury to the carotid and subclavian arteries or to the jugular and subclavian veins, pseudoarthrosis of the clavicle in the setting of clavicular osteotomy, and wound infection. Rarely, a wound hematoma or airway edema may result in respiratory compromise, and the patient must be monitored closely for evidence of airway insufficiency and swallowing dysfunction.

59.8.5 Postoperative Care

Most of our patients are discharged on postoperative day 2 or 3. The affected arm is immobilized in a sling for 3 weeks, at which point physical therapy is initiated to prevent joint stiffness and contractures. The patient is seen every 3 months in the clinic, and pain control is generally not a challenge when acetaminophen or ibuprofen is used. Other authors advocate the prolonged use of a cast placed in the operating room with subsequent use of a sling for several months before the initiation of physical therapy.

59.8.6 Outcomes

The results of surgery depend not only on the severity of the injury but also on the extent of root avulsions. Recovery typically begins within 2 to 10 months after surgical intervention and may continue until the patient is 5 years old. A 1995 report by

Gilbert et al of 178 cases treated with nerve reconstruction showed excellent results for repairs in children who had Erb palsy with regard to shoulder and elbow function; in 54 children with global palsy, reinnervation of the lower trunk achieved useful finger flexion in 75% of cases.¹¹² Multiple authors have demonstrated that neurologic improvement occurs in 75 to 95% of patients undergoing surgical reconstruction, with most achieving antigravity strength in the shoulder and/or elbow.^{29,60,79,102,113} Because the goal of surgery is not only to restore function but also to prevent permanent changes in the denervated muscle that may create long-term orthopedic deformities, the objectives include the following: stabilization of the shoulder through reinnervation of the supraspinatus and deltoid muscles, restoration of elbow flexion with reactivation of the biceps, and improvement of median nerve sensory function in cases of lower or total palsies in preparation for future secondary reconstruction procedures.¹¹⁴ Boome and Kaye published results including antigravity strength in 95% of the deltoid and 80% of the biceps muscles in patients following surgery; Laurent et al found that 85 to 95% of patients recovered antigravity strength above the elbow and noted a 50 to 70% recovery rate distal to the elbow.^{41,58,102} In our own series, those patients undergoing exploration and repair for upper plexus lesions achieved better results than those having surgery for lower plexus injuries.⁸⁶

59.8.7 Secondary Reconstruction

Up to 35% of infants and children with chronic NBPP commonly experience specific secondary deformities at each joint due to the unopposed contraction of innervated muscle groups, the presence of joint contractures, and the occurrence of abnormal stressors affecting the upper limbs.^{8,10} A review by Zancolli et al reported rates of secondary deformities of 72% for internal rotation contracture of the shoulder, 62% for flexion contracture of the elbow, 69% for supination contracture of the forearm, and 27% for ulnar deviation of the wrist and varying types of finger paralysis.¹¹⁵ Secondary reconstructions are often performed when such patients attain a rehabilitation plateau. The most common presentation is internal rotation contracture at the shoulder due to muscular imbalance between the active internal rotators and the paralyzed external rotators in patients with upper plexus injuries. Management by orthopedic surgeons includes serial clinical and radiologic assessments, muscle releases and muscle or tendon transfers, rotational osteotomies, and later shoulder arthrodesis. Grossman et al published their experience in infants aged 11 to 29 months with brachial plexus birth injuries. They used a late combined reconstruction of both the upper brachial plexus via end-to-side neuroorrhaphies and the shoulder via subscapularis slides with or without glenohumeral joint reduction and capsulorrhaphies; their findings of improvement in all patients of at least two grades on a modified Gilbert scale suggest that some children presenting late with persistent neurologic deficits and concomitant shoulder deformities may benefit from this type of simultaneous treatment.¹¹⁶ Weakness of elbow flexion may be addressed with a bipolar latissimus dorsi pedicle muscle

transfer or a functional muscle transfer performed in two stages. Extension deficit or elbow flexion contracture is also common and may be due to cross-innervation and muscle imbalance (stronger biceps than triceps) following spontaneous recovery from Erb palsy; because this is frequently observed in association with internal rotation contracture of the shoulder, surgical treatment of the shoulder deformity will typically improve the elbow contracture.^{117,118} Additionally, joint splinting, muscle or tendon release, and extension osteotomy of the distal humerus may be necessary. The usual birth palsy forearm deformity of slight pronation does not require intervention because the hand is in a functional position; the supination posture seen in patients with global palsy, however, may require biceps tendon rerouting, interosseous membrane release, and rotational osteotomy of the radius or proximal radioulnar arthrodesis.^{119,120} Finally, the lack of wrist extension in patients with upper plexus palsies is frequently reconstructed with a flexor carpi ulnaris or radialialis muscle transfer; the wrist instability observed in some patients with total paralysis is treated with arthrodesis after skeletal maturity is achieved.¹²¹

59.9 Conclusion

Despite increased awareness of the etiology and risk factors and improved obstetric techniques, the incidence of birth-related brachial plexus palsy has not declined in recent years. Although many neonates with birth palsy attain spontaneous recovery within weeks of the occurrence, others fail to improve with conservative therapy. We favor a process of close and frequent follow-up in our multidisciplinary clinic, with a recommendation for surgery earlier than 3 months in cases of total plexus palsy. We have demonstrated that the motor examination at 3 months of age is predictive of a favorable outcome if antigravity strength of the deltoid, biceps, and triceps muscles is present; such patients are managed with physical therapy alone. Similarly, we have shown that strength testing at 6 months of age is predictive of a poor functional outcome if antigravity strength in the aforementioned muscle groups is not achieved; surgical intervention is recommended in these cases. Patient evaluation includes a detailed neurologic examination, chest radiography, EMG, and MR imaging of the cervical spine and brachial plexus. The surgical approach is tailored to each patient's specific injuries, and repair strategies include neurolysis, neuroma resection and grafting, and nerve transfers; intraoperative electrophysiology may aid in the determination of the ideal reconstructive technique. We have recently used a decellularized peripheral nerve allograft in place of a sural nerve autograft with reduced operating time, a closer size match between graft and brachial plexus neural elements, and improved postoperative pain control due to the absence of leg incisions. The outcomes of primary brachial plexus reconstructions have been shown to be positive, with most patients making functional gains, particularly in the setting of upper trunk injuries. For those patients with chronic joint deformities due to unopposed muscle activity and contractures, secondary orthopedic surgery in the form of tendon releases, muscle transfers, osteotomies, or arthrodesis procedures may be necessary.

Pearls

- Despite the fact that most birth-related brachial plexus injuries are mild and improve after conservative management, the rates of spontaneous complete recovery are not as high as once believed.
- Although controversy exists regarding the optimal timing for surgical intervention, close follow-up and careful patient selection, combined with the use of microsurgical techniques, have achieved excellent functional outcomes in patients with pediatric brachial plexus palsies.
- Early surgery (within 3 months) should be considered for patients with global palsy, and a lack of antigravity strength in the deltoid, biceps, and triceps muscles at 6 months of age is an indication for primary operative reconstruction.
- A variety of repair options exist, including nerve grafting and neurotization, and the combination of detailed anatomical knowledge, MR imaging findings, and intraoperative electrophysiology allows the surgeon to tailor the repair to each patient's needs.
- The use of biodegradable nerve guidance channels and decellularized human donor peripheral nerve allografts offers an alternative to autologous sural nerve grafts; a randomized controlled trial comparing these entities is likely indicated.
- Parent counseling is critical throughout the process regarding expectations; the goal of primary surgery is to improve the functional capabilities of the arm, recognizable benefits may not appear for up to 6 months, and outcome is determined only after several years of recovery.
- Patients should be seen in a multidisciplinary brachial plexus clinic because many will manifest secondary sequelae of birth-related brachial plexus injuries, such as joint contractures, and will benefit from early orthopedic evaluation and intervention.

60 Principles of Pediatric Spinal Column Trauma

Zachary L. Hickman, Michael McDowell, and Richard C. E. Anderson

The unique anatomical characteristics of the developing spinal column change dramatically from infancy through childhood and into adolescence. These anatomical characteristics directly influence spinal biomechanics, which subsequently influence the response of the pediatric spine to physiologic and pathologic forces. Although prevention is the most effective means to combat pediatric spinal column injuries, a thorough understanding of these relationships is necessary to provide optimal care to children following vertebral column trauma.

This chapter addresses the underlying principles of pediatric spinal column trauma without focusing on specific injury types or the neurologic outcomes of injury. Specifically, the epidemiology, developmental anatomy, biomechanics, initial management, and diagnostic imaging pertaining to traumatic injuries of the immature spinal column are discussed. Additionally, information on the general principles of external and internal immobilization in the treatment of these injuries is included. Specific types of traumatic injury affecting the pediatric spinal column—including injury description, clinical presentation, radiographic diagnosis, and appropriate treatment—are discussed at length in the next chapter.

60.1 Epidemiology

The epidemiology of pediatric spinal column trauma is influenced heavily by patient age, which is closely associated with the incidence of injury, etiology and mechanism of injury, male-to-female ratio of injured patients, the vertebral level most likely to be injured, and the injury pattern.

60.1.1 Frequency

Occurring less frequently than in adults, pediatric spine injuries account for only 5 to 7% of all spine injuries that present to major medical centers.¹ The incidence of spine injury in children less than 19 years of age in the United States is approximately 20 injuries per million per year.¹ There is a seasonal variation in the incidence of pediatric spinal column trauma in North America, with a peak in the summer months from June to September and an additional increase in incidence during the winter holidays at the end of December and beginning of January.²

60.1.2 Etiology

The etiology of traumatic injuries to the pediatric spinal column varies depending on the age of the patient. Overall, in North America, motor vehicle accidents comprise the single most common cause of injury. In younger children (birth to 9 years of age), falls and pedestrian-versus-vehicle accidents account for as many as 75% of injuries.^{1,3,4} In children 10 to 14 years of age, motor vehicle accidents become more prevalent and account for 40% of cases, with falls and pedestrian accidents decreasing in frequency. In late adolescence (ages 15 to 17 years), motor vehicle accidents predominate as the leading cause of spinal column injury, accounting for more than 70% of cases in some

series. Sports-related injuries also become more frequent, and sports are the second most common etiology in this age group.^{1,3-6}

60.1.3 Gender

The male-to-female ratio of children with spinal column injuries varies with age, in concordance with the shift in etiology. In the youngest age group (birth to 9 years of age), the male-to-female ratio (1.1 to 1.3:1) is the smallest because pedestrian accidents tend to affect both genders equally, whereas boys are slightly more susceptible to falls.^{1,3,6} The ratio becomes significantly higher as one approaches the 15- to 17-year-old group (2.3 to 2.5:1), presumably because of a propensity of males to participate more frequently in aggressive sports and reckless driving.^{1,3,6}

60.1.4 Level of Injury

The vertebral level of injury in pediatric patients with spinal column trauma is strongly correlated with age, as predicted by the biomechanics of the immature spine. Numerous studies have demonstrated that the majority of spinal cord and vertebral column injuries occur in the cervical region within this age group.⁷ Two large series of pediatric spinal column injuries reported that the injuries were located in the cervical spine in almost two-thirds of patients (61%), followed by lumbar (14%), thoracolumbar (14%), and thoracic locations (11%).^{3,7} In particular, younger children are more likely to have upper cervical spine injuries, and as patient age increases, the most frequently injured level moves progressively caudal. Upper cervical and craniovertebral junction (CVJ) injuries are two to three times as frequent in children less than 3 years old than in older children and adults.^{3,6,8} In contrast to upper cervical injuries, whose frequency is largely influenced by age, lower cervical and thoracic injuries occur with approximately equal frequencies in both younger (birth to 9 years) and older (10 to 17 years) children because maturation of the spine at these regions occurs much more gradually than at the CVJ.^{6,9} Thoracolumbar and lumbar injuries are primarily lesions of adolescence. Of important consideration in pediatric spinal column trauma is the high incidence of multilevel contiguous (26 to 34%) and noncontiguous (6 to 16%) injuries.^{1,3,10,11} Subaxial cervical spine injuries involving multiple levels are more common in children 8 years of age or older than in younger children.¹² This highlights the need to survey the entire vertebral column in every child who presents with a spinal column injury.

60.1.5 Injury Pattern

Pediatric spinal column trauma is typically classified according to radiographic findings on plain X-ray and computed tomography (CT). Magnetic resonance (MR) imaging is generally less useful in the initial classification of injury types but has utility in the assessment of stability through a more detailed examination

of the associated soft tissues. Based only on skeletal information from imaging with X-rays and CT, four injury patterns are seen in children with spinal column trauma: (1) fracture with subluxation, (2) fracture without subluxation, (3) subluxation without fracture (purely ligamentous injury), and (4) spinal cord injury without radiographic abnormality (SCIWORA).¹³ Although an oversimplification, there is a rough correlation with the degree of instability inherent in this classification: fractures with subluxation are generally unstable; fractures without subluxation may or may not be unstable, depending on the amount of associated ligamentous injury; subluxation without fracture is by definition unstable, although the instability may not manifest immediately but instead later, as a delayed or progressive kyphotic deformity. SCIWORA is a very rare form of radiographically occult instability that is not demonstrable on imaging with conventional X-rays or CT. In the vast majority of cases, however, radiographic abnormalities are seen on MR imaging. Immobilization measures should be undertaken to prevent possible recurrent, progressive, or catastrophic injury.

Age profoundly affects the injury pattern within the pediatric population. In general, younger children (0 to 9 years) are most likely to have a purely ligamentous injury or SCIWORA, whereas older children (10 to 17 years) are more likely to have fractures with or without associated subluxation.^{1,3,14} In children with cervical spine injuries, the incidence of fracture is approximately 20 to 25% in the 0- to 8-year range versus 70 to 80% in children older than 13 years.¹⁵ Despite these numbers, it is important to note that although vertebral column fractures are less frequent in younger children, they are not uncommon; in some series, the incidence of fracture in children 0 to 9 years old with spinal column trauma has been reported to be as high as 50%.^{1,3}

In addition to the influence of age on the pattern of spinal column injury, there is a significantly higher incidence of neurologic injury in younger versus older children. The degree of neurologic compromise has been shown to correlate with the presence of subluxation. As such, children having fractures without subluxation tend to have fewer neurologic injuries (20 to 25%) than those with fracture and subluxation or subluxation without fracture (purely ligamentous injury) (>50%).³ Furthermore, among children with spinal cord injury (SCI), younger children are more likely to experience severe SCI.^{1,3} In most case series of pediatric spine trauma, the numbers of patients who are neurologically intact and those with SCI are approximately equal.^{1,3-6}

60.2 Embryology

Embryogenesis of the spinal column occurs in six separate but overlapping phases: (1) gastrulation, (2) condensation, (3) reorganization, (4) membranous proliferation, (5) chondrification, and (6) ossification. Congenital malformations are generally the result of errors during one of the first five phases, whereas the ossification phase is the most important with regard to the response of the vertebral column to trauma and its subsequent management.

Gastrulation occurs during the second week of embryogenesis, when the embryo is converted from a two-layered to a three-layered structure containing ectoderm, mesoderm, and

endoderm. This process begins with formation of the primitive streak at the caudal end of the embryo. As the primitive streak subsequently regresses, mesodermal cells from the Hensen node ingress through a primitive pit to form the midline notochord.^{16,17} The elongating notochord is flanked on each side by newly developed somitic mesoderm; together, these tissues ultimately form the axial skeleton (the intervertebral disks and vertebrae, respectively).

Once in final position, the somitic mesoderm aggregates into discrete, bilaterally paired blocks of tissue, called somites, in a process termed condensation. Both the notochord and somite pairs develop and mature in a rostral-to-caudal direction. The maximum number of somites in the human embryo is generally reported to be 42 to 44, although no more than 38 or 39 are required for formation of the axial skeleton.¹⁸

Reorganization involves the development of two segments within each somite: a ventral sclerotome, which contributes to the axial skeleton, and a dorsal dermomyotome, which becomes the dermis and subcutaneous tissues of the back and the dorsal trunk musculature.

The membranous phase of spinal column development begins during the fifth week of embryogenesis. Sclerotomal cells from each somite pair migrate toward the midline and surround the notochord ventrally and the neural tube dorsally. The vertebral centrum is formed by the merging of these cells on either side of the notochord and becomes visible in human embryos shortly thereafter. Craniocaudal polarity begins during somite formation and is restricted to the sclerotomal portion of the somite.¹⁹ The dorsal arch of each vertebra appears to be exclusively derived from the caudal, more densely packed, half of the sclerotome. Most evidence tends to support the concept of resegmentation, in which each somite pair directly contributes to the formation of two adjacent vertebral centra.^{20,21} This accounts for the observation that each spinal nerve passes caudal to its corresponding pedicle.

Chondrification centers appear within the sclerotomes during the sixth embryonic week. The annulus of the intervertebral disk is produced from the condensation of cells from perinotochordal tissues, while physaliphorous cells of the notochord form the central nucleus pulposus. The anterior longitudinal ligament and posterior longitudinal ligament also form during chondrification.

The ossification phase begins in the eighth week of embryogenesis and continues until adolescence.²² It is the most relevant phase of spinal embryogenesis with regard to the ability of the pediatric spine to withstand traumatic forces. The total number of ossification centers that form within each vertebral segment is still the subject of debate; however, most authors argue for three primary ossification centers: one for the vertebral centrum and one on each side for the dorsal vertebral arch. The ossification centers on each side of the dorsal arch subsequently form three progressively independent zones of ossification: one each for the pedicles, lamina, and transverse processes. The junction of the ventral and paired posterior ossification centers occurs at the neurocentral joint. Importantly, the neurocentral joint lies within the vertebral body, not at the junction of the pedicle with the body. Thus, the centrum, combined with the more ventral portions of the dorsal ossification centers, gives rise to the vertebral body. The terms *centrum* and *vertebral body* are therefore not strictly synonymous.

Cartilaginous zones subsequently appear cranial and caudal to the ventral ossification center at the cartilaginous end plates. The ring apophysis, a C-shaped structure, forms at the periphery of the cartilaginous end plates, between the developing intervertebral disk and the expanding ossification center of the vertebral centrum. By 11 to 14 years of age, foci of ossification appear within the ring apophysis and become confluent by 15 years of age, forming the radiographic ring. The ring apophysis fuses with the vertebral centrum during middle to late adolescence. This is particularly relevant since during childhood and adolescence the unfused ring apophyses may fracture in response to trauma, which can simulate a herniated disk with nerve root impingement, but is less likely to respond to conservative therapy.²³

The CVJ develops from the four occipital sclerotomes (somites 1 through 4) and the first and second cervical sclerotomes (somites 5 and 6). The occipital bone, clivus, and occipital condyles form from the four occipital sclerotomes (somites 1 through 4), with the condyles, paracondylar processes, and ring of the foramen magnum arising from the fourth occipital sclerotome (somite 4). The atlantoaxial complex forms from the fourth occipital sclerotome (somite 4) and the first and second cervical sclerotomes (somites 5 and 6).

Chondrification of the CVJ begins by embryonic day 45, and the cartilaginous anterior arch of C1 appears by day 50 to 53.²³ The anterior arch of the atlas is not ossified in 80% of newborns, and ossification is completed between 6 and 24 months postnatally. A synchondrosis is occasionally present in the anterior arch midline and should not be confused with a fracture.

The odontoid process separates from the atlas between the sixth and seventh weeks of embryogenesis.²⁴ Fusion of the odontoid process to the axis body at the dentocentral synchondrosis begins at about 4 years of age and is completed by 8 years; however, it has been known to remain visible on lateral radiographs in 50% of children up to 11 years old.²⁵ A common radiographic misinterpretation is that of the dentocentral synchondrosis as a type II odontoid fracture; however, the location of the synchondrosis is actually below the anatomical base of the odontoid. Injury to this area in young children is usually not technically a fracture, but rather epiphysiolysis of the dentocentral synchondrosis. The apical ossification center is generally visible by age 3 and fuses to the rest of the odontoid process by age 12. The apical synchondrosis can often be misinterpreted as a type I odontoid fracture. Failure of ossification of the apical synchondrosis is termed *ossiculum terminale persistens* (or *os avis*) and is not considered to be a pathologic condition.

60.3 Biomechanics

60.3.1 General Principles

The developing spine has several unique anatomical and physiologic properties that result in biomechanics that are significantly different from those of the mature adult spine. The main biomechanical difference between the pediatric and adult spine is that the developing spine is inherently more malleable to physiologic and pathologic forces and thus can withstand considerable movement between vertebral segments without damage, but at the cost of providing less protection to the underlying spinal cord.

The developing spine undergoes a biomechanical maturation at approximately 8 to 9 years of age, after which it more closely resembles that of adults.^{14,25–27} Evidence indicates that this transition takes place more abruptly in the upper cervical spine than in the lower cervical or thoracolumbar spine.^{3,6,27} The single most important concept in spinal biomechanics is that of stability. Instability has been defined by White and Panjabi as “loss of the ability of the spine under physiologic loads to maintain its pattern of displacement so that there is no initial or additional neurological deficit, no major deformity, and no incapacitating pain.”²⁸ Current models to predict injury have important limitations, particularly with respect to the pediatric spinal column. Few studies have directly investigated the biomechanics of the developing spine; therefore, many assumptions regarding its biomechanics are extrapolations from adult clinical and laboratory data, and these are viewed as particularly inaccurate with regard to the CVJ.

Despite these limitations, several general biomechanical premises and predictions relating to the developing pediatric spine have been suggested.²⁹ First, the malleability of the developing spinal column is increased by its more elastic ligaments, so that it is less likely to sustain fractures and ligamentous rupture when subjected to extrinsic forces but more likely to result in SCIWORA. Second, because it is more malleable, the pediatric spine undergoes more intervertebral displacement in response to extrinsic forces, affording less protection to the spinal cord, making SCI possible in the absence of fracture or subluxation. Third, the most unstable region of the developing spinal column is the upper cervical spine. Trauma to this region should result in fewer fractures but more severe SCI in young children than in older children and adults. Finally, the pattern of SCI in older children (more than 8 years old) should closely resemble the patterns seen in adults, with lower cervical injuries being more common.

60.3.2 Craniovertebral Junction

The occipitoatlantoaxial (O–C2) complex functions as the biomechanical unit of the CVJ. Interacting together as a single unit, the occipitoatlantal (O–C1) and atlantoaxial (C1–C2) joints control movement of the head in relation to the subaxial spine. The atlas (C1) functions as a biconcave washer wedged between the occipital condyles and the superior articulating facets of the axis (C2). The articulation between the occipital condyles and C1 (O–C1) is cup-shaped in the sagittal plane and tilted medially in the coronal plane. This orientation allows up to 20 degrees of flexion–extension and 8 degrees of lateral bending at the joint.²⁸ Further extension at O–C1 is limited by contact of the posterior arch of the atlas with the opisthion at the base of the skull.³⁰ Lateral bending of more than 8 degrees in either direction is inhibited by the contralateral O–C1 joint capsule. The oblique orientation of the O–C1 articulation precludes all but 4 degrees of rotation to either side at this joint.^{31,32}

Although essentially no lateral bending occurs at C1–2, the articulation between the lateral masses of C1 and C2 is biconcave in the sagittal plane and tilted laterally in the coronal plane, allowing a large degree of axial rotation centered on the odontoid process.^{28,33} Rotation at C1–2 ranges from 32.2 to 47 degrees to one side and accounts for up to 60% of the

rotation of the entire cervical spine.^{34–36} The first 20 to 30 degrees of head rotation occurs predominantly at the C1–2 joint, during which C1 moves independently of C2. As head rotation passes beyond 30 degrees, the C1–2 joint capsules and alar ligaments begin to reach the limit of their ability to stretch and C2 begins to follow C1 in rotation, but C1 continues to rotate faster than C2.^{31,34} The maximal degree of rotation between C1 and C2 is reached at approximately 47 degrees. Subsequent head turning is then accomplished by rotation of the subaxial spine. It is important to note that axial rotation is coupled to other motions within the CVJ. Maximal rotation is associated with 1.7 to 4.9 degrees and 3 degrees of lateral bending to the opposite side at O–C1 and C1–2, respectively.³⁶ Rotation is additionally coupled to extension, with up to 13 degrees of extension at O–C1 and 6 degrees at C1–2. Finally, because of the biconvex articulation between C1 and C2, downward translation occurs at this joint with rotation. Before spinal maturation, there is exaggerated motion at the articulation between the anterior arch of the atlas and the odontoid process. Flexion–extension of up to 20 degrees can occur at C1–2 because of physiologic overriding of the anterior arch of C1 along the dorsally curved odontoid process, particularly in very young children (younger than 3 years old), in whom the apex of the odontoid process is not yet ossified. The normal atlantodental interval (ADI) is less than 5 mm in children before spinal maturation (less than 8 years), compared with a normal value of less than 3 mm in adults. Twenty percent of normal children younger than 8 years have an ADI between 3 and 5 mm.²⁵

Stability of the CVJ is provided by several major elements: the cup-shaped O–C1 articulation and its associated capsular ligaments, the tectorial membrane, the alar ligaments, the odontoid process, and the transverse portion of the cruciate ligament.^{37–39} The transverse ligament is the thick horizontal portion of the cruciate ligament and is the primary constraint to posterior translation of the odontoid into the spinal canal. The tectorial membrane is a continuation of the posterior longitudinal ligament and functions to hold the body of C2 firmly to the clivus and anterior rim of the foramen magnum. Flexion at the CVJ is limited initially by contact between the basion and odontoid process. The tectorial membrane limits additional flexion as the basion slides forward and downward over the odontoid tip. Extension at the CVJ is also limited by the tectorial membrane and through contact between the opisthion and the posterior arch of the atlas. The paired alar ligaments, which run obliquely from the posterolateral surface of the odontoid to the medial occipital condyles, impart stability to lateral bending and rotation.³⁴ Studies have demonstrated that disruption of the tectorial membrane results in excessive flexion–extension and longitudinal displacement (> 1 cm) of the basion from the odontoid process. Compromise of the alar ligaments results in increased lateral bending and rotation. Frank occipitoaxial subluxation occurs when both the tectorial membrane and alar ligaments are disrupted.³⁹ In vivo clinical MR imaging data in children have demonstrated that involvement of the tectorial membrane is a critical threshold for instability in injuries involving the CVJ.⁴⁰ Larger paraspinous muscles have also been shown to contribute to the stability of the CVJ and are frequently involved in isolated or soft-tissue injuries.^{40,41}

The CVJ is the area of the pediatric spine that is most vulnerable to injury and potential instability. Injury to the O–C2 complex is the most common cervical spine injury in children less than 10 years of age.⁴² Several factors contribute to this susceptibility. First, articulations in the CVJ of a child are anatomically more predisposed to motion than those in adults. Second, as in the subaxial spine, the major stabilizing ligaments and paraspinous muscles are less developed and more elastic. Third, before approximately 8 years of age, the dentocentral synchondrosis between the odontoid process and the body of C2 is unfused. Generally, odontoid fractures in young children are actually epiphysiolysis of the growth plate at the dentocentral synchondrosis.⁴³ Congenital or chronic anomalies of the CVJ, such as os odontoideum and occipitalization of the atlas, can result in vulnerability to injury despite relatively minor trauma. The fulcrum of the cervical spine in infants and young children lies within the O–C2 complex as a consequence of the relatively large head size and short neck. Injuries to this region in children are mostly ligamentous or soft-tissue disruptions, rather than fractures, and are highly unstable.

60.3.3 Subaxial Spine

The stability of the subaxial spine is determined by (1) the ability of the vertebral bodies, facet joints, and intervertebral disks to withstand compressive forces and (2) the ability of spinal ligaments to withstand tensile forces.^{44,45} The pediatric subaxial spine is inherently more mobile than the adult spine, allowing considerably more movement at each vertebral segment in response to extrinsic forces. Several factors account for this hypermobility, including: (1) anterior wedging of the immature vertebral bodies, facilitating forward movement of adjacent motion segments^{14,25,26,46,47}; (2) shallow and more horizontally oriented facet joints, particularly in the upper cervical spine, requiring less force to elicit translation or flexion–extension^{14,25,26,46,47}; (3) absence of the unciniate process in children less than 10 years old, resulting in less restriction to lateral and rotational movements in the subaxial cervical spine⁴⁷; (4) more elastic spinal ligaments and joint capsules^{46,47}; (5) intervertebral disks that are more expansile in the longitudinal axis as a result of a higher water content^{48,49}; (6) epiphysiological growth zones at the vertebral end plates that split readily from the vertebral centrum under moderate shear forces⁵⁰; and (7) underdeveloped paraspinous muscles and a disproportionately large head that predispose to large degrees of motion in response to flexion–extension forces.

Within the subaxial spine, the upper cervical region is particularly hypermobile and is most susceptible to injury from flexion forces. The fulcrum for maximal flexion–extension in the subaxial cervical spine is at C2–3 in infants and young children and moves progressively caudal with increasing age until spinal maturity is reached.^{47,51,52} By 5 to 6 years of age, the fulcrum is at C3–4, whereas in adolescents and adults, it is located at C5–6. The elasticity of the interspinous ligaments in the developing spine is inversely proportional to age, accounting for the higher incidence of radiographic pseudosubluxation in the upper cervical spine of young children, most commonly at C2–3, but also seen at C3–4.^{53,54} Normal sagittal intervertebral translations of up to 4 mm can occur at C2–3 in children less than 12 years old. A 24% incidence of moderate to marked C2-on-C3 subluxation

has been demonstrated in children between 1 and 7 years old, whereas 46% of children less than 8 years old had 3 mm or more of anterior–posterior motion of C2 on C3 on flexion–extension studies.²⁵ Greater degrees of subluxation in the upper cervical spine should be considered unstable, and the normal upper limit of translation is 3 mm in the remaining subaxial spine. Children 12 years of age and older should not have physiologic motion greater than 3 mm.

60.4 Initial Evaluation and Treatment

Spinal column injury should be suspected in any child after trauma from an appropriate mechanism of injury (i.e., motor vehicle accident, fall, sporting accident) or with posttraumatic neurologic deficit. Initial management in the field and emergency department should always focus on maintenance of the airway, breathing, and circulation. The maintenance of adequate perfusion and blood oxygen levels immediately following trauma is of the utmost importance and may be more beneficial than any subsequent pharmacologic or surgical intervention.

During initial resuscitation efforts, appropriate immobilization of the patient's spine should be employed to prevent additional injury. In older children and adolescents, standard back board and cervical spine immobilization techniques can be used. In young children, however, the disproportionately large head may result in flexion of the cervical spine when the patient is immobilized in the supine position.⁵⁵ This should be avoided by bolstering the torso with padding or using a specialized board with a recess for the occiput. Use of a cervical collar is often problematic in infants; they are often best immobilized with the head and torso temporarily taped to the board. An underappreciated cause of avoidable distraction following immobilization is an inappropriately sized cervical collar. Log rolling should be used to move and position children with suspected spine injuries for diagnostic studies.

Several mechanisms of injury are significantly associated with spine injuries and should prompt complete screening radiographs. These include significant fall, pedestrian-versus-motor vehicle accident, abdominal lap seat belt injury, ejection from a motor vehicle, and suspected child abuse. Additionally, any child presenting with neck or axial back pain, neurologic deficit, or reduced mental status and an appropriate traumatic mechanism should be assumed to have a spinal column injury until it is proved otherwise. Several cutaneous findings that are associated with spinal column injuries include seat belt bruises of the abdomen and neck, subcutaneous emphysema, displacement of the spinous processes, and tire tracks across the back. Given the high incidence of both multiple contiguous and noncontiguous spinal column injuries in several series, the discovery of a spine injury at any level should trigger radiographic screening of the entire spinal column.^{3,10,11} Once a determination has been made that a spinal column injury is present, the same principles that apply to adult spine trauma are employed: (1) a determination of biomechanical instability, (2) closed or open reduction (and decompression) if necessary, and (3) appropriate spinal immobilization (external or internal).

60.5 Diagnostic Imaging

The combined use of common imaging modalities, including plain radiographs, targeted fine-cut CT, and MR imaging allows the clinician to identify both osseous and soft-tissue injuries and to make a determination regarding resulting instability. Of particular importance in the pediatric population is obtaining an accurate diagnosis while minimizing the exposure of the developing child to ionizing radiation. Ultimately, the treatment of pediatric spinal column trauma is based upon the neurologic status of the patient, diagnostic imaging results, and degree of maturation of the spinal column.

Plain radiographs are the mainstay of initial diagnostic imaging in any child with suspected spinal column trauma. Although specific guidelines exist for the radiographic assessment of adults with suspected spinal column trauma, there is still controversy regarding the appropriate indications for screening radiographs in children. Proposed pediatric protocols are usually aimed at ensuring that clinically significant injuries are not missed, while simultaneously limiting exposure to ionizing radiation. A prospective multicenter study by Viccellio et al in 2001 used the National Emergency X-Radiography Utilization Study (NEXUS) criteria to evaluate for cervical spine injury in children younger than 18 years.⁵⁶ The authors defined five high-risk criteria, including: (1) midline cervical tenderness, (2) evidence of intoxication, (3) altered level of alertness, (4) focal neurologic deficit, and (5) painful distracting injury. If any one of these criteria was met, the patient was considered high-risk; however, if none was met, they were low-risk. Of 3,065 children in the study, 603 (19.7%) were defined as low-risk, none of whom ultimately had a documented cervical spine injury. Conversely, there were 30 (0.98%) cervical injuries in the group of children considered to be high-risk. The results of this study clearly demonstrate that application of the NEXUS criteria to children reduces the need for screening cervical spine radiographs by almost 20% without resulting in any missed injuries.

The necessity and utility of open-mouth plain radiographs in pediatric trauma patients have been questioned.^{57,58} Current evidence suggests that the open-mouth odontoid view may not be routinely needed in children less than 5 to 9 years old.^{57,58} There is agreement that open-mouth views should be attempted in children 9 years of age and older. Conversely, dynamic imaging is of particular importance in the assessment of pediatric spinal column trauma. Ligamentous injury is more common than osseous injury in children and cannot be excluded based on the demonstration of normal bony anatomy on static radiographs; therefore, flexion–extension imaging should be obtained for responsive and cooperative patients during initial screening if spinal column trauma is suspected. In children unable to tolerate this, ligamentous injury may be assessed by using MR imaging with fat-suppressed sequences, or dynamic imaging may be attempted in a delayed fashion. Because the sensitivity of MR imaging to detect edema associated with ligamentous injury is reduced after 48 hours from spinal column trauma, the study should be obtained within this time interval in order to be diagnostic.⁵⁹ Ligamentous injury may also be assessed in a delayed fashion in unresponsive patients by using dynamic imaging under direct fluoroscopic guidance. In such patients, MR imaging should still be considered to rule out

an occult compressive lesion before dynamic imaging is obtained because the patient's neurologic examination cannot be followed reliably during flexion and extension.

MR imaging should be obtained in all children with a neurologic deficit and should also be considered before closed reduction and external immobilization or operative reduction and fixation to assess the degree of canal compromise. If the patient has previously implanted ferromagnetic instrumentation or intra- or paraspinal bullet fragments, CT myelography can be substituted for MR imaging to exclude compressive lesions.

CT should be used judiciously in the pediatric population in order to minimize exposure to ionizing radiation. It is not recommended as a means to clear the entire cervical spine, but its targeted use is helpful in evaluating osseous structures that are poorly visualized on plain radiographs. Many radiographic determinants of spinal column instability are difficult to assess accurately on plain radiographs, and in these cases further imaging with CT may be warranted. If an injury is suspected on plain radiographs, fine-cut CT should be obtained through the suspicious and adjacent levels to better define the anatomy, to survey for adjacent fractures, and to detect areas of incomplete ossification that may influence operative management.

60.5.1 Radiographic Determinants of Craniovertebral Junction Instability

Plain radiographs provide the most practical method of determining instability at the CVJ. Several radiographic criteria have been developed based on distances between osseous structures as seen on X-ray imaging (► Fig. 60.1). When visualization of these structures is poor, accurate assessment of CVJ instability may require CT of the O–C2 complex. It is important to note that extrinsic forces, such as positioning and immobilization, in highly unstable CVJ injuries may influence the anatomical relationships of the bony elements following injury. In children, these forces tend to be flexion due to the large head size in relation to the torso and distraction from a cervical collar. Additionally, plain film measurements have traditionally exhibited variation in response to differing magnification from discrepancies in film-to-target distances. The Powers ratio, Lee X line, and C1–2:C2–3 ratio were originally designed as dimensionless measurements to address this issue. However, with the widespread use of digital radiographic collection and processing systems, this problem has been mitigated. When instability of the O–C2 complex is suspected, it is imperative to use the following criteria in combination to attain a complete and thorough assessment. Only one positive finding should be considered necessary and sufficient for a diagnosis of CVJ instability.

Occipital Condyle–C1 Joint Interval

The O–C1 joint interval (CCI) is the distance between the occipital condyle and the superior facet of C1 (► Fig. 60.1a). Based on plain films, Kaufman et al found that this interval in children should not exceed 5 mm between any opposing points of the joint articulation on lateral or anteroposterior views.⁶⁰ Interpretation of the CCI on X-ray is nearly impossible, however,

because of superimposition of the mastoids and the imperfect overlap of the two O–C1 joints.

This difficulty is overcome with thin-cut CT. Using this modality, Pang et al established 4 mm as the upper limit of normal for the CCI in children.^{61,62} In a series of 89 normal children, the mean combined CCI for all 178 joints was 1.28 ± 0.26 mm, with no single CCI larger than 1.95 mm.^{61,62} Sagittal–coronal variation of the CCI is approximately 12%, and left–right variation is less than 3%. No individual measurement in any projection exceeded 2.5 mm. By using 4 mm as the upper limit of normal for the CCI, Pang et al subsequently demonstrated that at least one and usually both O–C1 joints were separated in all children with proven atlanto-occipital dislocation (AOD) regardless of Traynelis classification.⁶³ These children often had horizontal displacement or fractures of the O–C1 joint in addition to longitudinal separation. Coronal reconstruction through the occipital condyles demonstrates the true extent of AOD, with asymmetry suggesting a rotary component to the displacement. The CCI is the only measurement that directly measures the O–C1 articulation and is considered by most authors to be the single most reliable diagnostic criterion for O–C1 instability.

Dens-Basion Distance

The dens–basion (DB) distance of Wholey et al is the oldest criterion for determining O–C1 instability and is the distance between the tip of the odontoid process and the basion in the sagittal plane (► Fig. 60.1b).⁶⁴ The upper limit of the DB distance is 5 mm in adults and between 10 and 12.5 mm in children.⁶⁵ The marked difference in the DB distance with age is attributable to the incomplete ossification of the apical dens in children.⁶⁴ Recent data exclusively from children indicate that the normal value is less than 12.5 mm; in 11 children with proven AOD, all DB distances were greater than 14 mm.⁶⁵ One significant problem with the DB distance that has historically limited its utility is that its measurement on plain X-ray is influenced by the film-to-target distance. Additionally, variable ossification of the apex of the odontoid process between 2 and 12 years of age makes application of the DB distance potentially problematic in children. Finally, the DB distance varies with flexion, extension, and the application of axial traction in normal subjects. Nevertheless, a DB distance of more than 14 mm in a child should be considered diagnostic of O–C1 instability.

Basion–Axial Interval

First reported by Harris et al in 1994 to describe the translational relationship between the occiput and C2 in AOD, the basion–axial interval (BAI) is the distance between the basion and a line extending rostrally from the dorsal cortex of the odontoid process (the posterior axial line) (► Fig. 60.1c).⁶⁶ In adults, the BAI normally extends from 12 mm anterior to 4 mm posterior to the posterior axial line (+12 mm to –4 mm) and does not change with flexion or extension. In children, the BAI is usually less than 12 mm anterior to the posterior axial line, but the basion does not extend posterior to the posterior axial line as it does in adults.⁶⁶ The BAI exceeds +12 mm in Traynelis type I (anterior) AOD, whereas it is less than –4 mm in Traynelis type

Fig. 60.1 Radiographic determinants of craniocervical junction instability. (a) Occipital condyle–C1 (O–C1) joint interval (CCI). The mean CCI is determined by measuring and averaging the distance across the joint space at four equidistant points (white arrowheads) along the occipital condyle and C1 superior articulating facet. The CCI is considered by most authors to be the single most reliable criterion of O–C1 instability, and a value ≥ 4 mm is considered abnormal.^{61,62} (b) Dens–basion distance. Measured from the dens (D) to the basion (B), distances of 5 and 12.5 mm are the upper limits of normal in adults and children, respectively.⁶⁴ A value > 14 mm in children is diagnostic for O–C1 instability.⁶⁵ (c) Basion–axial interval (BAI). This is the distance between a vertical line drawn through the basion and the posterior axial line (PAL; white arrowheads); it is usually $< + 12$ mm (anterior to the PAL) in normal children.⁶⁶ (d) Powers ratio. The ratio is determined by dividing the distance between the basion (B) and the midpoint of the posterior arch of C1 (C) by the distance between the opisthion (O) and the midpoint of the anterior arch of C1 (A).⁶⁸ Normal values typically are 0.77 ± 0.09 , with a value > 1 indicative of anterior atlanto-occipital dislocation (AOD).^{29,69} (continued)

III (posterior) AOD.⁶³ Used in conjunction with the DB distance, the BAI is more accurate in adults than either the Powers ratio or the Lee X line.⁶⁷ In young children, however, the posterior cortical margin of the odontoid process is anteriorly sloped, artificially moving the reference point for the BAI forward. As a result, the BAI may underestimate the degree of anterior occipital translation in AOD.

Powers Ratio

The distance from the basion to the posterior arch of the atlas (BC) divided by the distance from the opisthion to the anterior arch of the atlas (OA) is the Powers ratio (► Fig. 60.1d).⁶⁸ In the normal population, the ratio is 0.77 ± 0.09 , with all ratios over 1 being abnormal and indicative of anterior (type I) AOD.^{29,69}

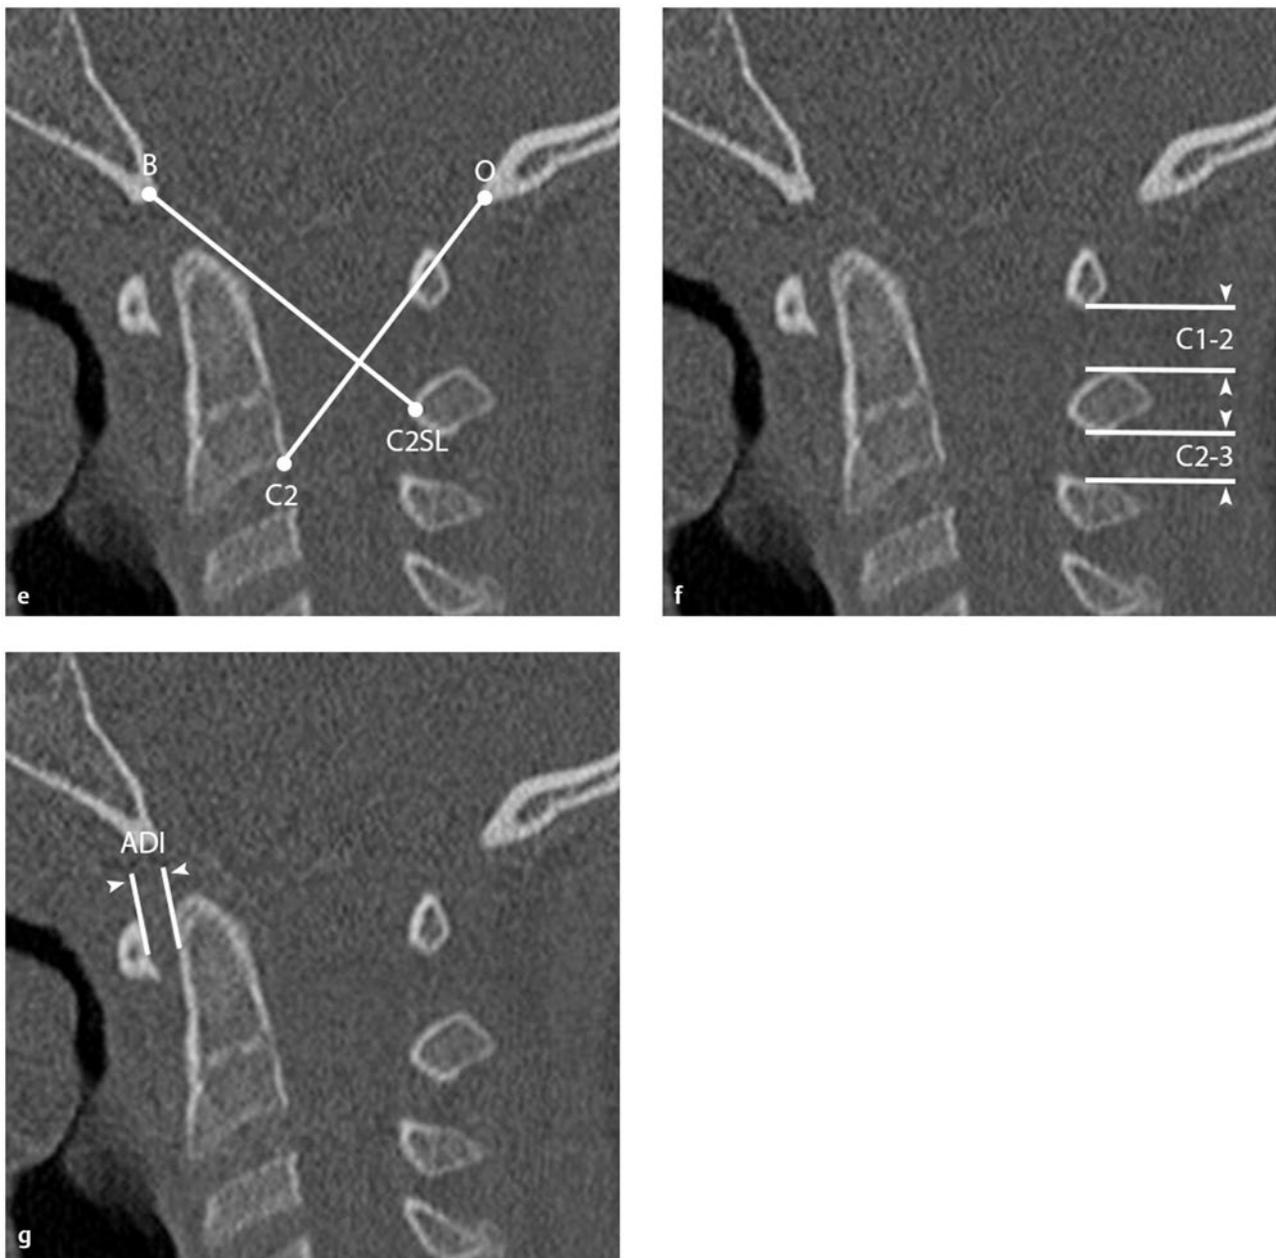

Fig. 60.1 (continued) (e) Lee X line. Lines from the basion (B) to the midpoint of the C2 spinolaminar line (C2SL) and from the opisthion (O) to the posteroinferior body of C2 are drawn.⁷⁰ The first line should tangentially intersect the posterosuperior dens, and the second should intersect the highest point on the C1 spinolaminar line. At least one intersection should be present; if neither is present, AOD should be suspected. This is of limited utility in children because it requires a fully formed odontoid process to be accurate. (f) Atlantodental interval (ADI). The distance between the anterior arch of C1 and the ventral surface of the dens (white arrowheads) should be < 3 mm in adults and 5 mm in children older than 8 years.^{28,54,71,72} Values greater than these suggest transverse ligament compromise. (g) C1-2:C2-3 ratio. This is obtained by dividing the shortest distance between the posterior arch of C1 and the spinous process of C2 by the shortest distance between the spinous processes of C2 and C3 (white arrowheads).⁴⁰ Damage to the tectorial membrane may result in ratios > 2.5.

In anterior AOD, the ratio is increased because BC widens while OA shortens. Two major disadvantages of the Powers ratio are a failure of the measurement to properly diagnose posterior and longitudinal (types II and III) AOD and the fact that in children up to 70% of lateral cervical spine films may not reveal the exact position of the opisthion.⁶⁹ The use of sagittal CT reconstructions to properly localize the opisthion may be necessary.

Finally, anomalies of the posterior arch of C1 and the foramen magnum can make the Powers ratio invalid.

Lee X Line

Proposed by Lee et al in 1987, the X line does not require calculation.⁷⁰ On a lateral cervical radiograph or sagittal CT, two

lines are drawn: one from the basion (B) to the midpoint of the C2 spinolaminar line (C2SL) and a second from the postero-inferior body of C2 to the opisthion (O) (► Fig. 60.1e). The result is an X in which the basion-to-C2SL line should tangentially intersect the posterosuperior dens and the C2-to-opisthion line should tangentially intersect the highest point on the C1 spinolaminar line. At least one intersection should be present; if both lines fail to intersect, then AOD should be suspected. The Lee X line is of limited utility in children, however, as its validity depends on atlantoaxial integrity and a fully developed odontoid process.

C1–2:C2–3 Interspinous Ratio

The C1–2:C2–3 interspinous ratio of Sun et al is determined by dividing the shortest distance between the lower cortex of the posterior C1 ring and the upper cortex of the C2 spinous process by the corresponding shortest distance between the spinous processes of C2 and C3 (► Fig. 60.1f).⁴⁰ This ratio was developed because instability of the CVJ may manifest as separation of C1–2 as well as O–C2. The proposed mechanism whereby AOD results in an abnormal C1–2:C2–3 ratio is that a loose O–C1 articulation allows forward and downward pressure of the occipital condyle on the anterior rim of the superior facet of C1, resulting in separation of the posterior arch of C1 away from C2.⁴⁰ Ratios greater than 2.5 suggest damage to the tectorial membrane.⁴⁰ The C1–2:C2–3 ratio has several limitations. First, the relationship between the occipital condyles and the anterior rim of C1, and therefore the C1–2 interspinous distance, can be altered to an unpredictable degree by the mode of temporary immobilization used following injury. Second, concomitant rupture of the transverse ligament causes C1–2 subluxation, altering and invalidating the ratio, as will congenital anomalies of the posterior arches of the upper cervical vertebrae. Third, the ratio may be artificially enlarged by the use of muscle relaxants.

Atlantodental Interval

The most commonly used radiographic criteria to assess instability at C1–2 is the distance between the dorsal cortex of the anterior arch of C1 and the ventral aspect of the odontoid process, the atlantodental interval (ADI) (► Fig. 60.1g). Widening of the ADI results from failure of the transverse ligament. The normal upper limit of the ADI is 3 mm in adults and 5 mm in children less than 8 years old.^{71,72} In the setting of a C1 fracture (Jefferson fracture), rupture of the transverse ligament should also be suspected if the bilateral overhangs of the C1 lateral masses on an anteroposterior view total 7 mm or more.⁷³

60.5.2 Radiographic Determinants of Subaxial Spine Instability

The guidelines for determining overt instability in the pediatric subaxial spine are not well defined. Stability can be predicted radiographically in two main ways: (1) by using a simplified biomechanical model as either a two- or three-column structure or (2) based on the degree of segmental angulation or horizontal displacement at the suspected injury levels. Both the two- and three-column models, however, are biomechanical

simplifications developed from studies of the mature adult spine. The developing pediatric spine, with its unique anatomy and biomechanics, is not ideally represented by either of these models.

Radiographic assessment of the amount of horizontal displacement and degree of segmental angulation at the levels of suspected injury can provide additional information. Although the criteria are still poorly defined, more horizontal displacement, but less angulation, is typically allowed in a normal, stable pediatric spine because of its inherently greater ligamentous laxity and elastic recoil compared with an adult spine. In children younger than 8 years, horizontal displacement of up to 4.5 mm should be considered normal.²⁹ In children older than 8 years, horizontal displacement of more than 3.5 mm is generally considered unstable. On radiographic imaging of the subaxial spine, the upper limit of angulation between adjacent vertebrae that suggests ligamentous injury in children is commonly reported as 7 degrees. If a child has angulation that is less than 7 degrees with severe pain and muscle spasm, external immobilization (i.e., a hard cervical collar) should be considered until satisfactory dynamic studies can be obtained to rule out instability. For children with angulation between 7 and 11 degrees and without a neurologic deficit, flexion–extension studies should be obtained to assess stability. If the degree of angulation is unchanged on dynamic imaging, the study should be repeated in several days to eliminate confounding from muscle spasm. If repeated imaging demonstrates less than 11 degrees of angulation and the study is satisfactory (i.e., the child is without muscle spasm and is able to obtain at least 30 degrees of flexion–extension), external immobilization should be pursued until dynamic radiographs are obtained to confirm healing of ligamentous structures. If ligamentous injury is chronic or will not heal with immobilization, surgical stabilization may be necessary.

Cervical Spine Clearance

Currently, no national guidelines exist for clearance of the cervical spine in children after trauma. The most recent American Association of Neurological Surgeons and Congress of Neurological Surgeons joint guidelines for the management of pediatric cervical spine and spinal cord injury stated that there was insufficient evidence to establish standards of care for the diagnosis of cervical spine injuries in children.⁵⁹ Despite this, several protocols have been published to assist in clearance of the cervical spine in children.^{74–76} The use of defined protocols decreases the time needed to clear the cervical spine in children,⁷⁷ reduces the number of missed injuries,⁵⁶ and facilitates clearance by non-neurosurgical medical staff.^{74,76} Obtaining a consensus for a universal protocol is challenging, however, given the involvement of numerous different health care providers (neurosurgeons, trauma surgeons, orthopedic surgeons, emergency department physicians, and others) who have differing training and experience.

Brockmeyer et al recently published the results of a pilot study examining the prognostic value of plain radiographs, flexion–extension radiographs under fluoroscopy, CT, and MR imaging in clearing the pediatric cervical spine after severe trauma.⁷⁵ The authors determined that within this high-risk population there is an overall low prevalence (4%) of instability. Plain radiographs, flexion–extension radiographs, and CT all

had very high rates of sensitivity and specificity in screening for unstable cervical injuries. MR imaging also demonstrated a high sensitivity but had a more significant false-positive rate.

We previously published a protocol for cervical spine clearance in communicative children between 3 and 18 years old to facilitate clearance by non-neurosurgical personnel.^{74,78} The protocol is based on the NEXUS data demonstrating that approximately 20% of children fall into a low-risk category for cervical injury after trauma.⁵⁶ If initial screening radiographs are abnormal, a neurosurgical consult is obtained. If imaging is normal, the NEXUS criteria are then applied to facilitate clearance of the cervical spine. Communicative children with normal radiographs and meeting the low-risk NEXUS criteria are cleared. Failure to meet all five of the low-risk criteria in a child with a normal neurologic examination prompts additional investigation with dynamic imaging. The cervical spine is cleared if the results are normal. If abnormal, the patient is referred to neurosurgery for assistance with clearance. Our protocol simplifies the method used for pediatric cervical spine clearance, allowing clearance in approximately 60% of cases to be performed by non-neurosurgical personnel without any missed injuries. Abnormal plain or dynamic radiographs, or an abnormal neurologic examination, should prompt immediate neurosurgical referral and further imaging with CT and MR imaging, as appropriate.

Clearance of the cervical spine in noncommunicative children, including those between 0 and 3 years of age, is particularly difficult because it is usually not possible to apply the NEXUS criteria in these patients. In particular, the incidence of ligamentous injury is higher in younger, noncommunicative children than in older, communicative children.^{12,74,79,80} To address this issue, we subsequently developed a protocol for cervical spine clearance in this population.⁷⁶ The overwhelming majority of noncommunicative children can be cleared without the need for either CT or MR imaging, and flexion–extension radiographs are only rarely needed. In more than 80% of cases, the cervical spine is able to be cleared based on a combination of normal plain radiographs and a benign clinical examination. In more than 500 evaluations, the protocol resulted in no missed injuries.

60.6 External Immobilization

The vast majority of children with spinal column trauma do not require surgical intervention and can be effectively managed with external immobilization. Examples of injuries that are often amenable to initial treatment with external immobilization include the following: C1 (Jefferson) fractures in which there is minimal ligamentous disruption and the transverse ligament remains intact (per the “rule of Spence”⁷³ with a C1 lateral overhang of 7 mm or less on odontoid view radiographs or coronal CT); atlantoaxial rotatory subluxation/atlantoaxial rotatory fixation (AARS/AARF); acute odontoid fractures with minimal displacement or angulation; C2 pedicle (hangman) fractures; purely ligamentous injuries of the subaxial cervical spine without gross instability; osseous anterior and posterior column injuries of the subaxial spine without gross instability or kyphotic deformity; thoracolumbar compression fractures; thoracolumbar burst fractures without neurologic deficit or

instability; flexion–distraction injuries without neurologic deficit or significant ligamentous injury (kyphosis < 20 degrees); low-grade spondylolysis/spondylolisthesis; and SCIWORA. The presence of a progressive neurologic deficit from a compressive lesion and evidence of gross instability are contraindications to primary management with external immobilization alone and are indications for surgical intervention. Early mobilization of a child after placement in an external immobilization device is important. The intensity and duration of external immobilization must be customized to each child. These depend upon the injury type, degree of reduction required, patient compliance, activity level, and evidence of radiographic fusion.

60.6.1 Craniocervical and Cervical Immobilization

Halo Ring and Vest

A properly fitted halo ring with pins and vest provides the most rigid external immobilization of the cervical spine and is the gold standard orthosis in children with an unstable cervical injury.^{81,82} Newer halo orthoses without pins are also available. A halo is particularly suited for immobilization of the CVJ and upper cervical spine. An advantage of the halo system is that it causes the least interference with mandibular motion and eating; it is the only external cervical orthosis that does not require chin support.⁸³ Additionally, the halo ring provides a means to apply traction in order to obtain either closed or open reduction. Disadvantages include complications such as pin loosening or infection, the potential for injury (i.e., skull fracture) in children prone to detrimental behavior (frequent falls or altercations during which the halo may be used by another as a handle or by the wearer as “attack antlers”), and the morbidity associated with placement and a prolonged duration of use (i.e., difficulties with hygiene).

A halo ring is best applied in young children under general anesthesia or conscious sedation with cardiopulmonary monitoring. In compliant adolescents, it may be applied with only local anesthesia if necessary. Halo immobilization can be achieved even in very young children who are at least 1 year old. The forces used must be reduced and dissipated through more contact points when a halo ring is applied in a child less than 6 years old. In infants younger than 2 years, 10 pins (as opposed to 4 pins in older children and adults) should be used and finger-tightened only. From ages 2 to 6, the number of pins can be reduced to 8, starting with 2 inch-pounds of torque for a 2-year-old with an increase of 1 inch-pound per year up to age 6. Past this age, 4 pins may be used and should be tightened to 8 inch-pounds of torque, as in adult patients. Although they are necessary to prevent iatrogenic skull fracture, a disadvantage of using more pins in younger children is that there are fewer unused holes on the ring to allow pin changes in cases of infection or loosening at the pin site. Pins may loosen by up to 4 inch-pounds of torque within the first day after insertion or after halo vest uprights are attached. Pins should therefore be tightened 24 hours after insertion and again after attachment of a halo vest and uprights if this is not done at the same time as ring placement (such as when halo traction is attempted). Because most cervical injuries are unstable in flexion, it is often preferable to immobilize the spine in mild extension; however,

some children may be displeased with this positioning. In these cases, a “military” posture, in which posterior translation is substituted for extension, may be better tolerated. In the rare cases of very young children who are too small for a vest, a halo ring attached to rods incorporated into a thoracic cast may be required.

The incidence of complications associated with halo immobilization is higher in children than in adults; however, the majority of these are pin loosening and pin site infections.^{84,85} The higher rate of pin loosening in children is likely related to the thin calvaria. Skull fractures can be avoided by using more pins for placement, as described above, and by placing anterior pins in the superolateral orbital buttress above the eyebrows.⁸⁴ The calvaria is thicker in this location, and such placement also avoids inadvertent injury to the supraorbital and supratrochlear nerves. The incidence of pin loosening and infection correlates with the duration of halo fixation. One study reported an overall complication rate of 68% in children undergoing halo immobilization.⁸⁶ The anterior pins were responsible for the majority of pin site complications, with younger children more likely to experience pin loosening and older children more likely to experience pin site infections.⁸⁶ Alignment slippage also affects children with halos more than adults. This may be due to undiagnosed pin loosening or the fact that children are less likely than adults to appropriately protect their halos.²⁹

The age of the patient largely determines the appropriate management of loose halo ring pins. Retightening of loose pins should be avoided in young children because they typically have thin calvaria with soft bone surrounding the pin site as a result of accelerated osteoclasts. Pin retightening may result in full-thickness penetration of the skull and intracranial abscess formation.⁸⁷ In these children, loose pins should be removed and replaced with a pin at a new site. In contrast, pin retightening is generally safe in older children as long as resistance can be felt during tightening.

Pin site infections are more common in children than in adults, with a reported incidence in one series of 31% versus 6%, respectively.⁸⁴ Infected pin sites should be managed by removing all scabs to allow drainage and by cleaning thoroughly with 10% hydrogen peroxide solution four times daily. Oral antibiotics are appropriate treatment for mild superficial infections if the pin site is still tight. If pin loosening is noted, or if the infection is more severe and associated with erythema, swelling, purulent drainage, pain, or headaches, the pin should be removed and replaced at a new site and intravenous antibiotics considered to prevent osteomyelitis of the skull. Screening CT should be considered to assess for intracranial abscess.^{87–89}

Minerva Brace

The Minerva brace does not use cranial pin fixation and is a useful method of cervical immobilization in children who cannot tolerate halo placement.⁹⁰ The mandibular strap allows movement to facilitate eating; therefore, the rigidity of fixation is inferior to that of a halo. To address this, a hybrid of the halo and Minerva brace has been developed that incorporates a molded cranial ring as opposed to pins and attaches to a molded vest with malleable rods.⁹¹ Other disadvantages of the Minerva brace include a large surface area in contact with the molded brace that can result in skin irritation and breakdown,

and the ease with which children may escape from the brace compared with a halo. Additionally, a Minerva brace is not suitable for the application of traction to the cervical spine.

Rigid Cervical Collar

The rigid cervical collar is the most common and practical of cervical orthoses. Compared with a halo or Minerva brace, it provides less stability in the upper cervical levels but similar stability in the lower cervical spine. It is the orthosis of choice for the immediate cervical immobilization of anyone but infants or very young children in the acute trauma setting. A rigid cervical collar may also be used in children with cervical fractures, particularly of the subaxial cervical spine, that do not require surgery or the degree of rigidity afforded by a halo or Minerva brace. A hard collar provides adequate immobilization in compliant older children and adolescents following craniocervical or cervical internal stabilization and fusion. The main disadvantage of this type of orthosis is that it can be easily removed. Removal by younger children may be prevented by the use of duct tape.

Posted Cervical Orthoses

There are many additional types of cervical orthoses that attach to the thorax via buckles and straps and provide immobilization through the use of posts or cups that are secured to the occiput and mandible. The main benefits of these orthoses are that they provide a greater degree of fixation than a rigid cervical hard collar and are more difficult for children to remove. A prime example is the Guilford brace, which is advocated by Pang and colleagues for external immobilization in children with cervical SCIWORA.^{9,29,92} The limitation of middle and lower cervical spine flexion, extension, and rotation provided by the Guilford brace is similar to that of other cervicothoracic orthoses, as is its relative ineffectiveness at inhibiting lateral bending.⁸¹ The main advantage of the Guilford brace is that it can be customized within 24 hours to fit any child down to 1 year of age. The Guilford brace is also suitable for external immobilization following reduction of AARF.

Molded Shells

Shells made of molded thermoplastic materials are useful for neonates and infants who require external immobilization of the cervical or upper thoracic spine. These types of orthoses are designed to conform to the back of the torso and head and are secured to the patient with self-adhesive straps across the torso and forehead.²⁹ The open design allows nursing, changing, and placement in a car seat.

60.6.2 Thoracolumbar Immobilization

The two main types of orthoses used for external immobilization of the thoracolumbar spine are the Jewett brace and the molded thoracolumbosacral orthosis (TLSO). The Jewett brace is used to provide hyperextension in the treatment of traumatic kyphotic deformity. A TLSO is appropriate for external immobilization of the thoracolumbar spine when hyperextension is not required. A last resort for external immobilization in very young children who are not compliant with a TLSO is casting of the torso and legs.

60.7 Internal Stabilization and Fusion

60.7.1 General Principles

Children with traumatic spinal column injuries who present with progressive neurologic deficits or evidence of gross instability should undergo prompt surgical intervention. In some cases, such as a traumatic herniated disk or apophyseal avulsion fracture in which there is localized neural element compression without significant trauma to the rest of the spinal column, simple decompression may be all that is required. In many instances, however, surgical intervention will necessitate the incorporation of internal stabilization and fusion procedures to provide immediate immobilization of unstable spinal column segments. Examples of traumatic spinal column injuries in which internal stabilization and fusion should be considered include the following: AOD; C1 (Jefferson) fractures in which there is compromise of the transverse ligament (C1 lateral overhang of >7 mm on odontoid view radiographs or coronal CT); C1–2 (atlantoaxial) subluxation; AARS/AARF that involves anterior translation of the atlas (Field-Hawkins types II and III), is chronic, or is recurrent; odontoid fractures that cause spinal cord compression or that fail to fuse after external immobilization; hangman (C2 pars) fractures that cause significant ligamentous injury or that fail to heal after external immobilization; multiple thoracolumbar compression fractures with progressive kyphosis; thoracolumbar burst fractures with instability or neurologic deficit; flexion–distraction injuries with neurologic deficit or significant ligamentous injury (more than 20 degrees of kyphosis); fracture–dislocation injuries; and refractory, progressive, or high-grade spondylolysis/spondylolisthesis.

The primary benefit of internal instrumented fusion is immediate immobilization of the unstable segments of the spinal column. This reduces the risk for subsequent deformity, pain, and injury to the underlying spinal cord or nerve roots from progressive instability. Additionally, for those patients with injuries for which initial treatment with an external orthosis may be considered, internal stabilization and fusion often allow the elimination of, or a reduction in, the duration or degree of intensity of external immobilization. The primary disadvantages of instrumented fusion in children include the risks inherent to general anesthesia and the procedure itself, and poorly understood alterations of spinal growth in young children.

Operative intervention in children with a progressive neurologic deficit should be performed expeditiously to decompress the spinal cord or nerve roots and to maximize potential neurologic recovery. In children with no evidence of neural compression but with gross instability or malalignment, definitive surgical intervention is generally not as urgent as long as adequate immediate stabilization has been achieved. Any attempts at closed reduction should be performed manually in the operating room with the use of general anesthesia, fluoroscopy, and spinal cord monitoring (if available). In the setting of cervical cord compression or an unstable cervical spine injury, awake fiber-optic intubation is preferred, although vigorous resistance by a child may increase the risk for injury to the cervical cord. In these cases, fiber-optic nasotracheal intubation following the induction of general

anesthesia is a viable alternative. Prepositioning somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs) should be obtained following intubation when there is significant instability or spinal cord compression. SSEP and MEP monitoring should be continued after positioning and throughout the duration of the surgery, if possible.

In young children who still have a significant amount of spinal growth remaining, it is particularly important to limit the number of instrumented spinal segments. This should be balanced against the desire to select a fusion construct that will achieve the greatest immediate internal stability. In children, a greater burden is often placed upon the immediate strength of the instrumented fusion construct, particularly in those with upper cervical spine injuries. This is because non-halo orthoses are more frequently used postoperatively in this population given the higher complication rates seen with halo immobilization. Another issue of particular importance in pediatric patients undergoing internal stabilization and fusion is the inadvertent inclusion of normal adjacent segments into the fusion mass. Callus formation and subsequent fusion following violation of the periosteum and immobilization of the spine are more exuberant in children than in adults, particularly in the relatively immobile thoracic spine. The subperiosteal dissection of adjacent segment laminae and spinous processes and migration of fusion material into these sites are a likely cause of such “fusion creep.” This results in an unnecessary loss of mobility and a theoretically increased risk for adjacent segment degeneration resulting from a greater lever arm and increased stress at the ends of the fusion mass. Inadvertent incorporation of the occiput into an atlantoaxial fusion results in loss of up to 13 degrees of flexion–extension at the O–C1 joint, and inadvertent fusion of a cervical level below C2 results in loss of 8 to 17 degrees of flexion–extension and 8 to 12 degrees of rotation, depending on the level and the age of the patient.⁹³ Meticulous subperiosteal dissection limited as much as possible to the levels to be fused is the most efficient method to prevent inadvertent extension of the fusion mass.

Care must also be taken during dissection of the pediatric spine to avoid inadvertent entry into the spinal canal through the midline cartilaginous tissue between nonfused laminae, which is easily disrupted by monopolar electrocautery. The surgeon must be aware that the possibility of nonfused laminae exists despite maximal spinal column maturation and should not assume complete ossification at a given level despite complete ossification at other levels. Fusion of the laminae occurs postnatally; it begins in the lumbar spine, proceeds cranially, and is usually complete by 3 years of age. Nonfused laminae are most prevalent at the rostral and caudal ends of the spinal column, occurring at S1, L5, C1, C7, and T1, in order of decreasing frequency. In addition to careful dissection, a discerning review of the preoperative imaging may help prevent inadvertent entry into the spinal canal through a midline defect of the posterior elements. In addition to nonfused laminae, the spinous processes are often poorly formed before fusion of their secondary ossification centers, precluding the successful use of interspinous wiring techniques. Also, transverse process hooks are usually not a viable option in children because of incomplete ossification.

The use of autologous bone grafts in children undergoing internal stabilization results in increased fusion rates compared with the use of allograft only. When possible, the use of autograft should be considered, particularly when large structural bone grafts are required, such as for occipitocervical or atlantoaxial fusion constructs. Iliac crest remains the gold standard for autograft, although other autologous sources include the ribs, fibulae, and split-thickness occipital bone.²⁹

60.7.2 Craniovertebral Junction Instrumentation

Given the unique anatomy of the O–C2 complex, different techniques are required for internal stabilization and fusion of this region compared with the subaxial spine, including wire-graft techniques, C1–2 transarticular screws, Goel-Harms constructs, and odontoid screws. Given the high degree of flexion–extension at O–C1 and rotation and translation at C1–2, any fusion technique used at the CVJ must be able to adequately withstand forces directed in all four of these planes of motion.²⁹

Wire–Graft Techniques

Several techniques have been developed for C1–2 wiring given that the atlas lacks a spinous process for interspinous wiring and there is usually a large gap between the posterior arches of C1 and C2, so that the use of a structural bone graft is required to impart the necessary stability in extension unless the posterior arches can be firmly approximated. Additionally, the atlantoaxial joint subserves a high degree of rotation and translation; therefore, any C1–2 fusion construct must be able to withstand these forces as well.

Introduced in 1939, the Gallie fusion is the oldest published method for obtaining a C1–2 fusion construct through sublaminar wiring.⁹⁴ A single midline sublaminar wire is looped around the arch of C1 and the spinous process of C2, securing a structural bone graft positioned on the spinous process of C2 and against the dorsal aspect of the posterior arch of C1. The main disadvantage of this construct is that it lacks stability in both extension and rotation. Additionally, in children less than 12 years old, there is the potential for the midline wire to cut through the posterior arch of C1 at the midline synchondrosis.

The Brooks fusion, with modifications by Griswold et al in 1978, offers a greater biomechanical advantage than the Gallie fusion, obtaining stability in both flexion and extension and increased resistance to rotation and translation.⁹⁵ This construct is formed by passing bilateral sublaminar wires around the posterior arch of C1 and the laminae of C2. The wires are tightened over a corticocancellous bone graft that is “T-shaped” to prevent displacement into the spinal canal and wedged between the posterior arches of C1 and C2.⁹⁶ Stability in flexion is provided by the sublaminar wires, and in extension by the wedged bone graft.⁹³ Friction from the bone graft helps prevent rotation and translation at the atlantoaxial joint. In a more recent modification of the Brooks fusion, two separate bone grafts are placed between the posterior arches of C1 and C2 on either side of midline,⁹⁷ so that this fusion method can be used when the middle one-third of the posterior arch of C1 has been removed for decompression of the spinal cord. A disadvantage of this modification,

however, is that it requires the passage of two sublaminar wires (instead of one) around C1 and C2 on either side, potentially increasing the risk for cord injury during surgery.

The Dickman-Sonntag fusion is a combination of the Gallie fusion and the original Brooks fusion.⁹⁸ A single midline loop of wire is passed around the posterior arch of C1 and tightened around the spinous process of C2. This secures in place a structural bone graft that has been sized to fit snugly between the arches of C1 and C2, resting on the spinous process of C2. Advantages over the Gallie fusion are that in addition to stability in flexion from wiring, the Dickman-Sonntag fusion provides stability in extension from wedging of the graft between the posterior arches. Like the Brooks fusion, the Dickman-Sonntag construct prevents rotation and translation. An advantage of this technique over the Brooks fusion is that only a single loop of wire needs to be passed around the posterior arch of C1, where there is typically ample space. Therefore, it reduces the total number of sublaminar wires needed and completely avoids sublaminar passage at C2.

Instrumented Fusion

Instrumentation at the CVJ provides superior immediate stability compared with wiring techniques alone, allowing a reduction in the duration and intensity of postoperative immobilization. These techniques have been typically employed in older children who have a sufficiently developed anatomy to accommodate instrumentation; however, advances in instrumentation and techniques continue to allow hardware to be placed in progressively younger patients. Novel flow diagrams may assist with the selection of rigid internal fixation constructs in pediatric patients requiring occipitocervical or atlantoaxial stabilization.⁹⁹ Relatively long-term data suggest that there is no increased risk for cervical spinal deformity, subaxial instability, or significant growth inhibition in younger, compared with older, children following O–C2 or C1–2 fusion incorporating transarticular screw fixation.¹⁰⁰

Occipitocervical Fixation

Occipitocervical fixation is indicated in children with atlanto-occipital instability and generally consists of an occiput-to-C2 fusion. The main concern with fusion to the occiput in children is the relatively thin calvaria in comparison with that of adults. The occipital bone in young pediatric patients may be thick enough to enable sufficient screw purchase only in the midline keel or laterally near the mastoid processes. Plating systems that use screws with larger head diameters are useful to dissipate forces on the thin occipital bone. Additionally, an “inside-out” occipital screw technique has been developed that can be used in children to minimize the risk for intracranial injury from occipital screw placement.¹⁰¹ Postoperative immobilization with a rigid cervical collar is generally sufficient following occipitocervical fusion with rigid instrumentation.

C1–2 Transarticular Screws

Pioneered by Magerl in 1979, transarticular screws provide excellent stability in both rotation and translation across the C1–2 joint.¹⁰² The use of transarticular screws obviates the need for

postoperative halo immobilization in most cases, which is of obvious benefit in young children. Fusion rates are superior to those of wire-graft techniques with postoperative halo immobilization (95 to 98% vs. 80 to 86%, respectively).^{97,103,104} Wang et al reported a 100% fusion rate with no need for postoperative halo and no complications, compared with an 84% fusion rate reported by Lowry et al when fixation was obtained via wire-graft techniques and halo immobilization.^{105,106} Another advantage of transarticular screws is that they can be used for atlantoaxial fixation even in cases in which the posterior arches of C1 and C2 have been removed for decompression. If the arches of C1 and C2 remain intact, transarticular fixation can be supplemented with wire-graft techniques to afford even greater stability in flexion-extension.¹⁰⁷ Additionally, if subaxial spine fixation is needed, the construct can be easily extended to include lateral mass screws.

The main disadvantages of C1–2 transarticular screw fixation are that it is technically demanding and that the anatomy in young children may preclude safe screw placement. Preoperative planning of the screw trajectory is required, and intraoperative guidance with fluoroscopy or frameless stereotactic navigation is needed to prevent unnecessary complications, such as vertebral artery and neural injury.¹⁰⁸ When these precautions are taken, however, complication rates are quite low.^{98,103,104,108} The C2 isthmus is smaller in children than in adults, and its dimensions should be measured during preoperative screw planning to ensure that it is of adequate size to accommodate instrumentation. Screw trajectories should be simulated on stereotactic software before surgery to ensure safe placement. It has been demonstrated that the vertebral artery anatomy may prevent safe transarticular screw placement in one isthmus in 11 to 20% of cases, and in both in 4 to 5% of cases.^{108–110} Additionally, if there is a poor reduction of C1–2 subluxation with a significant offset of the articulating facet surfaces, there is a correspondingly higher incidence of screw malposition.¹⁰⁹

Goel-Harms Constructs

To address the disadvantages of C1–2 transarticular screw placement—namely, the degree of technical difficulty and cases in which the anatomy precludes safe placement—Harms and Melcher reported on their modification of the Goel construct, employing posterior atlantoaxial fixation with bilateral C1 lateral mass and C2 pars screws linked by metallic rods.^{111,112} Further modification with one or more C2 translaminar screws in place of pars screws is also possible. Another advantage of these constructs is that they can be used when a nonreducible C1–2 subluxation precludes transarticular screw placement. As with transarticular screw fixation, the concomitant use of wire and structural graft techniques is not required but may enhance immediate stability in flexion-extension and provide additional surfaces for osseous fusion. Preoperative screw planning should be undertaken in children to ensure that their anatomy will accommodate the available instrumentation, and screws should be placed under intraoperative fluoroscopic guidance.

Odontoid Screws

Type II odontoid fractures with an intact transverse ligament may be amenable to fixation via odontoid screw placement if

there is no excessive angulation or distraction of the fracture. An advantage of odontoid screw fixation over C1–2 transarticular screw placement for type II odontoid fractures is the preservation of physiologic motion at the C1–2 joint.

60.7.3 Subaxial Spine Instrumentation Sublaminar Wiring

Sublaminar wiring techniques in the subaxial spine involve the use of soft braided titanium cables or Mersilene (Ethicon, Somerville, NJ) tape that is looped bilaterally around adjacent laminae with structural bone grafts (i.e., autologous iliac crest) wired to the fusion surface.²⁹ Sublaminar wiring with structural graft techniques results in high fusion rates in children and has been shown to afford more stability than either interfacet or interspinous wiring.¹¹³ Care must be taken to prevent cortical violation of the laminae during dissection to reduce the incidence of the cables cutting into, or through, the bone.

Posterior Instrumented Fusion

In recent years, as a result of advances in surgical technique and instrumentation technology using lateral mass screws, pedicle screws, and derotating systems, posterior instrumented fusion of the pediatric spine has become commonplace. Posterior instrumentation allows decompression, reduction, and stabilization over a large number of segments, if required. Anterior instrumentation and fusion strategies are still used in specific circumstances but are much less common than posterior approaches. The main difficulties of instrumented fusion in children compared with that in adults include: whether a given patient's anatomy can accommodate the required instrumentation and withstand the stress applied by the construct, a smaller amount of bone surface for definitive fusion to occur, and the potential for alterations to spinal growth in young patients.

60.8 Conclusion

Spinal column trauma in the pediatric age group can result in neurologic deficit or spinal deformity. The injury level, pattern, and resulting stability are all heavily influenced by the unique anatomical characteristics and biomechanics of the developing spine. The prompt and accurate diagnosis of vertebral column injuries in children can be challenging because of an inability of young patients to accurately communicate, the unique radiographic appearance of the developing spinal column, and the inherent elasticity and recoil of the pediatric spine that may mask potentially unstable ligamentous injuries. The cervical spine, particularly the CVJ, is the most commonly injured region of the spine in children. Younger patients tend to have injuries at higher levels compared with older patients. Additionally, spinal column injuries in young children are more likely to be ligamentous, emphasizing the importance of dynamic imaging in properly obtaining a diagnosis. Fractures become more prevalent in older children and adolescents.

The majority of spinal column injuries in children ultimately do not require surgical intervention. Most are able to heal with external immobilization alone. Important considerations in the development of a treatment plan include the injury pattern and

stability, the neurologic status of the patient, the reducibility of the injury, the presence of compressive lesions, the likelihood of healing with external immobilization, and the degree of patient compliance with the treatment. Primary indications for surgical intervention include neurologic deficit from a compressive lesion or evidence of spinal column instability. Goals of surgery are neural decompression, reduction, and stabilization of the vertebral column. Advances in surgical technique and instrumentation technology continue to increase the options for operative intervention in children after spinal column trauma.

Pearls

- The injury level, pattern, and stability are directly influenced by the unique anatomical and biomechanical characteristics of the pediatric spinal column.
- The most important biomechanical principle in appropriate management of pediatric spinal column trauma is that of stability.
- The transition from an immature to a mature spine, in biomechanical terms, occurs at roughly 8 to 9 years of age.
- Spinal column trauma is more likely to result in ligamentous injury rather than fractures in young children; the older the child, the more likely that a given injury involves a fracture.
- Infants and young children are more likely than older children and adults to have injuries to the CVJ and upper cervical spine.
- In any child with a vertebral column injury, there should be a high suspicion for multiple contiguous and noncontiguous injuries.
- Dynamic imaging and MR imaging, when appropriate, are of particular importance in the diagnosis of pediatric spinal column trauma given the high incidence of purely ligamentous injuries.
- Distracting forces (e.g., traction) should be considered carefully in young children with cervical spine injuries given the high incidence of occipitocervical and atlantoaxial instability in this age group.
- The majority of spinal column injuries in children can be managed with external immobilization only.
- Surgical intervention is indicated for spinal column injuries resulting in neural compression or instability.
- Recent advances in surgical technique and instrumentation technology have increased the options available to neurosurgeons for the treatment of unstable spinal column injuries.
- The treatment of unstable injuries with rigid internal fixation and fusion often allows a reduction in the duration and intensity of external immobilization.

61 Specific Injury Patterns and Treatment of Pediatric Spinal Column Trauma

Zachary L. Hickman, Michael McDowell, and Richard C. E. Anderson

This chapter addresses the specific aspects of the diagnosis and appropriate management of the major classes of injury seen in pediatric spinal column trauma. Common presentations and the biomechanical implications associated with each injury type are discussed in the context of the unique anatomical characteristics specific to the immature spine. Although injury patterns throughout the entire developing spine are addressed, a particular emphasis is placed on craniovertebral junction (CVJ) and cervical spine injuries, as these are the most common within the pediatric population.

61.1 Specific Injury Types

61.1.1 Craniovertebral Junction Injuries

Atlanto-occipital Dislocation

Injury Description

Atlanto-occipital dislocation (AOD) involves traumatic separation of the occiput from C1 and is an injury primarily of the pediatric population, occurring more than twice as frequently in children as in adults (► Fig. 61.1 a–d). It is one of the most common fatal cervical spine injuries, resulting from high-energy acceleration–deceleration impacts, most often during motor vehicle accidents involving pedestrians. AOD is primarily a ligamentous injury; it is caused by either hyperextension or, less commonly, hyperflexion in combination with extreme rotation, lateral flexion, and distraction, which results in rupture of the O–C1 joint capsules and disruption of either or both of the tectorial membrane and alar ligaments.^{1–7} There are usually no fractures, although in older children and adolescents, stronger ligaments may result in avulsion fractures at the ligamentous attachments to the occipital condyles or the base of the clivus, as opposed to frank ligamentous rupture.^{3,4,6} There is often additional injury to the suboccipital and posterior cervical musculature and prevertebral intrafascial hemorrhage.

Clinical Presentation

Historically, AOD has been associated with a high incidence of at-the-scene mortality; however, increased resuscitation skills in the lay public, improved emergency medical service response times, better initial cervical spine immobilization, and more prompt diagnosis have led to an increasing number of survivors.^{8–13} Children with AOD generally present with cardiopulmonary failure and severe neurologic deficits resulting from supratentorial, brainstem, cranial nerve, and spinal cord injuries.^{14–18} Coma or severely altered mental status is common. Motor deficits in AOD vary depending on the level and degree of injury and range from subtle hemiparesis to flaccid quadriplegia. It is important to note that most survivors of AOD, including those with a severe initial presentation, such as flaccid quadriplegia, have incomplete injuries and ultimately may have a good outcome.

Radiographic Diagnosis

Radiographic findings on plain films may be subtle, and AOD should be suspected in any child involved in high-speed trauma, especially one presenting with cardiopulmonary instability and associated facial injuries. Because early diagnosis is paramount to mitigate additional neurologic injury, all patients with suspected AOD should undergo prompt initial radiographic screening with a lateral cervical spine plain film.

Historically, AOD has been classified according to the system developed by Traynelis et al in 1986, which defined three types based on the direction of displacement of the occiput with respect to the atlas: type I, with anterior dislocation; type II, with longitudinal dislocation; and type III, with posterior dislocation.¹⁹ The majority of children with traumatic AOD have a type I injury. Recently, use of the Traynelis classification system has largely been supplanted by use of the occipital condyle–C1 (O–C1) joint interval (CCI) of Pang et al for the diagnosis and classification of AOD (► Fig. 61.1a,b).^{20,21} A CCI of more than 4 mm in either the sagittal or coronal plane for one or both O–C1 joints is considered a positive finding. Alternatively, a Powers ratio of greater than 1 is always abnormal and is indicative of Traynelis type I AOD. A basion–axial interval of more than +12 mm is indicative of type I AOD, and a value of less than –4 mm represents type III AOD. The dens–basion (DB) distance of Wholey et al may also be used to assess for AOD, and values greater than 14 mm should be considered diagnostic.²²

Any patient with suspected AOD based on clinical presentation, compatible mechanism, or plain radiographic findings should undergo thin-cut computed tomography (CT) from the occiput to at least C2 with sagittal and coronal reconstructions. CT reconstructions through the O–C1 joint can more clearly demonstrate abnormal separation or translation of the articulation than plain films. However, it should be noted that if AOD is reduced at presentation, bony abnormalities may not be apparent on either plain films or CT scans.

AOD is commonly associated with other radiographic abnormalities on both CT and magnetic resonance (MR) imaging, including cervicomedullary subarachnoid hemorrhage, spinal cord injury (SCI) or compression, and traumatic brain injury (i.e., cerebral edema, contusions, traumatic subarachnoid hemorrhage, intraventricular hemorrhage, or diffuse axonal injury). MR imaging is useful when plain radiographs or CT is not diagnostic and may demonstrate disruption of the tectorial membrane or alar ligaments and hemorrhage or edema in the retropharyngeal and posterior soft tissues, as well as brainstem and spinal cord damage or compression (► Fig. 61.1c).

Treatment

The initial treatment for AOD begins in the field with aggressive cardiopulmonary resuscitation as needed. During resuscitation

Fig. 61.1 Atlanto-occipital dislocation. (a) Sagittal and (b) coronal reconstructed computed tomographic scans of the occipital condyle–C1 joint from a 4-year-old girl demonstrating an abnormally large occipital condyle–C1 joint interval (white arrowheads). (c) Sagittal fat-suppressed T2-weighted magnetic resonance image demonstrating associated spinal cord edema at the cervicomedullary junction and significant ligamentous injury. (d) Postoperative lateral radiograph from this patient demonstrating occipital condyle–C2 posterior fusion incorporating bilateral C1-2 transarticular screws.

efforts, the spine and head are temporarily immobilized in a neutral position, as discussed in Chapter 60 in the section on initial evaluation and treatment. In young children with a disproportionately large head-to-torso ratio, elevation of the

thorax with padding or blankets or the use of a specialized back board with a recess for the occiput prevents undue flexion of the neck and anterior dislocation. Immobilization with a rigid cervical collar should be maintained pending more definitive

treatment. If a properly fitting cervical collar is not available, the head of a young child may be temporarily immobilized by taping to the back board.

Following radiographic confirmation of AOD, if there is a reasonable chance of survival and meaningful neurologic recovery from associated supratentorial brain injuries, the child should undergo prompt external immobilization. AOD is exceedingly unstable, and the use of distracting cervical traction is contraindicated because it may result in additional cervicomedullary injury.^{23,24} Evolving brainstem findings following immobilization are suggestive of vertebral artery dissection.

Some authors have reported successful treatment and fibrous fusion in children with AOD by using only external immobilization in a halo vest.^{23,25–27} Others, however, have reported worsening neurologic deficits when internal stabilization was not pursued.⁹ Given that AOD is extremely unstable and there is a very real risk for delayed neurologic injury with inadequate immobilization, occipitocervical instrumentation and fusion should be strongly considered once the patient is medically stable and any associated brainstem swelling has begun to resolve, typically 5 to 7 days after injury. Because C1–2 instability cannot be independently elicited in the presence of AOD, longitudinal C1–2 instability should be assumed, and therefore internal fixation and fusion from the occiput to C2 is typically performed (► Fig. 61.1d).

Long-term stability is predicated on achieving bony arthrodesis across a wide area of the occipital bone and the posterior arches of both C1 and C2. Autologous structural bone graft, such as rib, iliac crest, or split calvarial bone, is the gold standard and is most commonly used. Given the high incidence of AOD in infants and very young children, the posterior elements may not be robust enough to accept internal fixation, although rigid internal fixation from the occiput to C2 has been reported in children as young as 18 months. If rigid internal fixation is not possible, then sublaminar fixation techniques with postoperative halo immobilization may be required to achieve adequate fusion rates.

Jefferson (C1) Fracture

Injury Description

First described by Sir Geoffrey Jefferson in 1920, fractures of the atlas (C1) result when axial compression is transmitted from the occipital condyles to the lateral masses of C1 (► Fig. 61.2).²⁸ Jefferson fractures are rare in children because the atlas is not completely ossified in this age group and the C1 ring contains a large amount of cartilage, allowing the dissipation of excessive axial loads.²⁹ The most common mechanisms of injury are falls and motor vehicle accidents. The posterior and neurocentral synchondroses of the atlas fuse at around 3 and 7 years of age, respectively.³⁰ In children, it is important to distinguish a Jefferson fracture from an unfused synchondrosis, which is generally not of any clinical significance.³¹ Alternatively, C1 fractures may occur through the synchondrosis and can be missed on plain radiographs.³⁰ Atlas fractures may be accompanied by disruption of the transverse ligament, resulting in atlantoaxial instability. There is a high incidence of associated C2 fracture.

Clinical Presentation

The classic presentation of a child with an atlas fracture includes neck pain, muscle spasm, decreased range of motion, and head tilt; the majority of patients have at least three of these four symptoms.²⁹ Neurologic deficit is rare because of the capacious size of the spinal canal at this level and the fact that pathologic axial loads result in widening of the C1 ring as it fractures.

Radiographic Diagnosis

The majority of atlas fractures can be diagnosed with plain radiographs or CT scans. CT has led to an increased recognition of these fractures in children (► Fig. 61.2a,b).³² On odontoid view radiographs, transverse ligament disruption is suggested if the sum of the total overhang of the C1 lateral masses on C2 is 7 mm or more (the “rule of Spence”). MR imaging can be used to further assess the integrity of the transverse ligament, if needed.

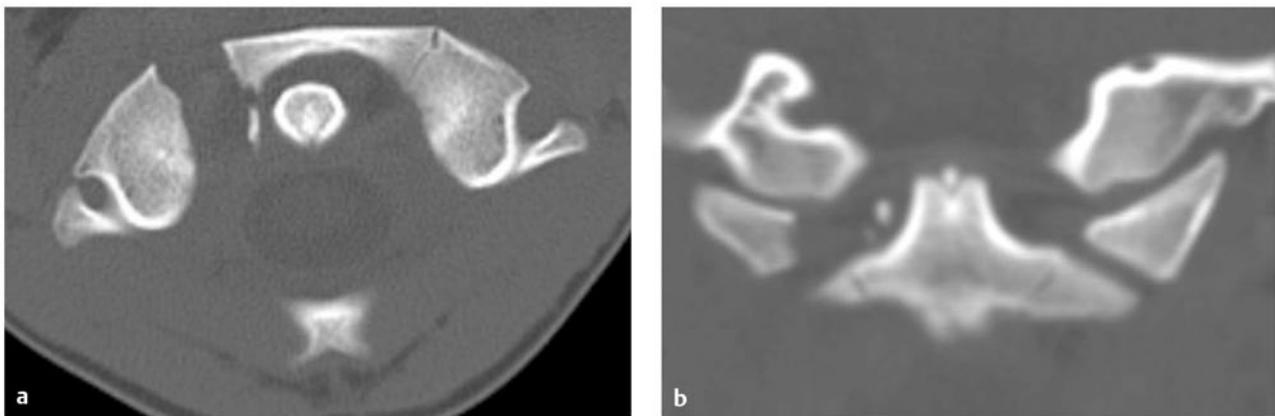

Fig. 61.2 Jefferson fracture. (a) Axial and (b) coronal computed tomographic (CT) scans demonstrating fracture through the right anterior arch and lateral mass of C1. If the sum of the total lateral overhang of the C1 lateral masses on C2 is ≥ 7 mm on odontoid view radiographs or coronal CT, then disruption of the transverse ligament should be suspected (the “rule of Spence”).¹¹⁹

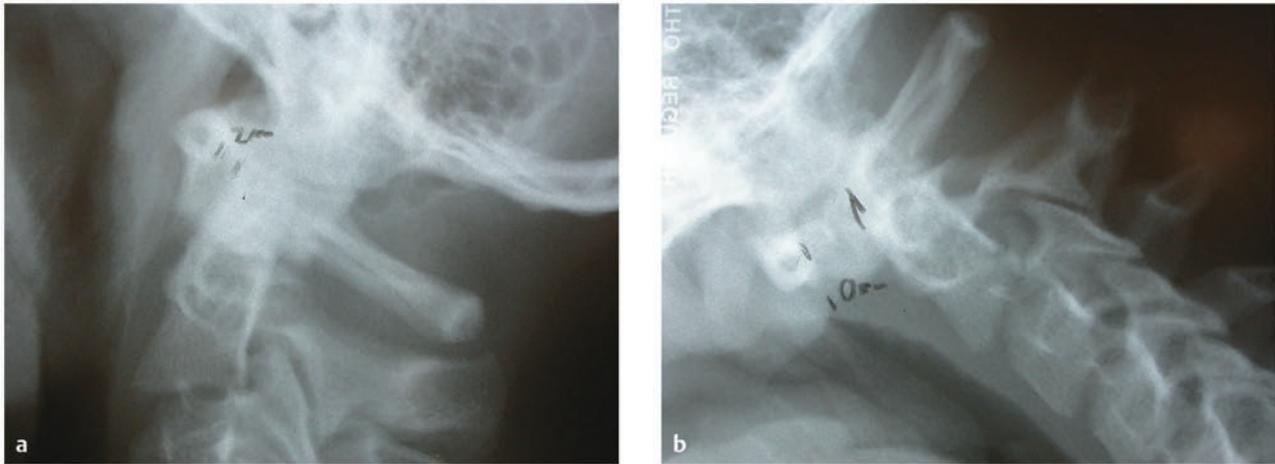

Fig. 61.3 Translational C1–2 subluxation. (a) Extension and (b) flexion radiographs demonstrating an atlantodental interval of 2 mm on extension and 10 mm on flexion, indicative of atlantoaxial instability in a 13-year-old boy following an assault to the head.

Treatment

The treatment of isolated Jefferson fractures with an intact transverse ligament is generally external immobilization in a rigid cervical collar, Minerva brace, or halo. If there is transverse ligament rupture and atlantoaxial instability, treatment should involve either halo immobilization or, rarely, C1–2 internal stabilization and fusion.

Translational Atlantoaxial Subluxation

Injury Description

Traumatic translational atlantoaxial (C1–2) subluxation is an extremely rare injury in children, often occurring as a result of a violent mechanism. There are few survivors (► Fig. 61.3, ► Fig. 61.4).^{33–36} The majority of affected children are 0 to 9 years old and often have purely ligamentous injury without fractures. In this age group, the dentocentral synchondrosis has less strength than the transverse ligament; therefore, epiphyseolysis of the odontoid process occurs more readily than transverse ligament rupture and translational C1–2 subluxation, partially accounting for the low incidence of this injury in children.³⁶ As such, traumatic translational atlantoaxial subluxation generally occurs under very specific circumstances and in the presence of predisposing factors. It is thought to result from disruption of the transverse ligament, allowing compression of the spinal cord between the odontoid process and posterior C1 arch. However, some autopsy studies have disputed this, reporting that injury to the C1–2 facet joints and capsules is more common than transverse ligament rupture in these patients.³⁴ A flexion mechanism is implicated in most cases of traumatic translational C1–2 subluxation³⁷ however, rare instances of posterior subluxation secondary to hyperextension or atlantoaxial distraction have been noted, even in the presence of a normal odontoid process and C1 ring.³⁸ Nontraumatic translational atlantoaxial subluxation is associated with developmental disorders that result in either laxity of the transverse ligament or odontoid hypoplasia (i.e., Down syndrome, Klippel-Feil syndrome, juvenile rheumatoid arthritis, Morquio syndrome, skeletal dysplasias).

Clinical Presentation

Like those with AOD, most children with traumatic translational C1–2 subluxation are victims of high-speed pedestrian–motor vehicle accidents.^{31,39,40} Patients frequently present at one of two extremes: with minor neck pain, C2 hypesthesia, and subtle myelopathy or with severe head injury and anoxic encephalopathy.⁴¹ Long-term survivors of traumatic translational C1–2 subluxation often have good neurologic outcomes, likely because of selected survival at the injury scene.

Radiographic Diagnosis

Translational atlantoaxial subluxation is most commonly diagnosed by an abnormally large atlantodental interval (ADI) on a lateral plain radiograph (► Fig. 61.3a,b). An ADI greater than 5 mm is considered abnormal in children younger than 8 years old, whereas 3 mm is the upper limit of normal in older children and adults.^{42–44} As the ADI exceeds 6 to 10 mm, the alar ligaments and tectorial membrane may become secondarily damaged and occipitoatlantal instability may ensue. The retropharyngeal soft tissues are usually widened on lateral plain films. If open-mouth odontoid views are obtained, it may be possible to visualize an avulsed C1 tubercle where the transverse ligament inserts onto the anterior C1 arch.⁴⁵ MR imaging may demonstrate rupture of the transverse ligament, with blood products, swelling, or rarely discontinuity of the ligament.^{46,47} Surgical treatment should be considered in patients with Down syndrome and an ADI of 6 mm or greater because 20 to 30% of these children will experience neurologic deterioration over time if intervention is not pursued.^{48–51}

Treatment

Because traumatic atlantoaxial subluxation is primarily an extensive ligamentous injury, the generally accepted treatment is C1–2 internal fixation and fusion (► Fig. 61.4a–d).^{39,41,52} Postoperative immobilization in a halo vest is recommended if nonrigid fixation is used,⁴⁵ but it may be deferred if C1–2 transarticular screws or other rigid internal fixation is employed.⁵³

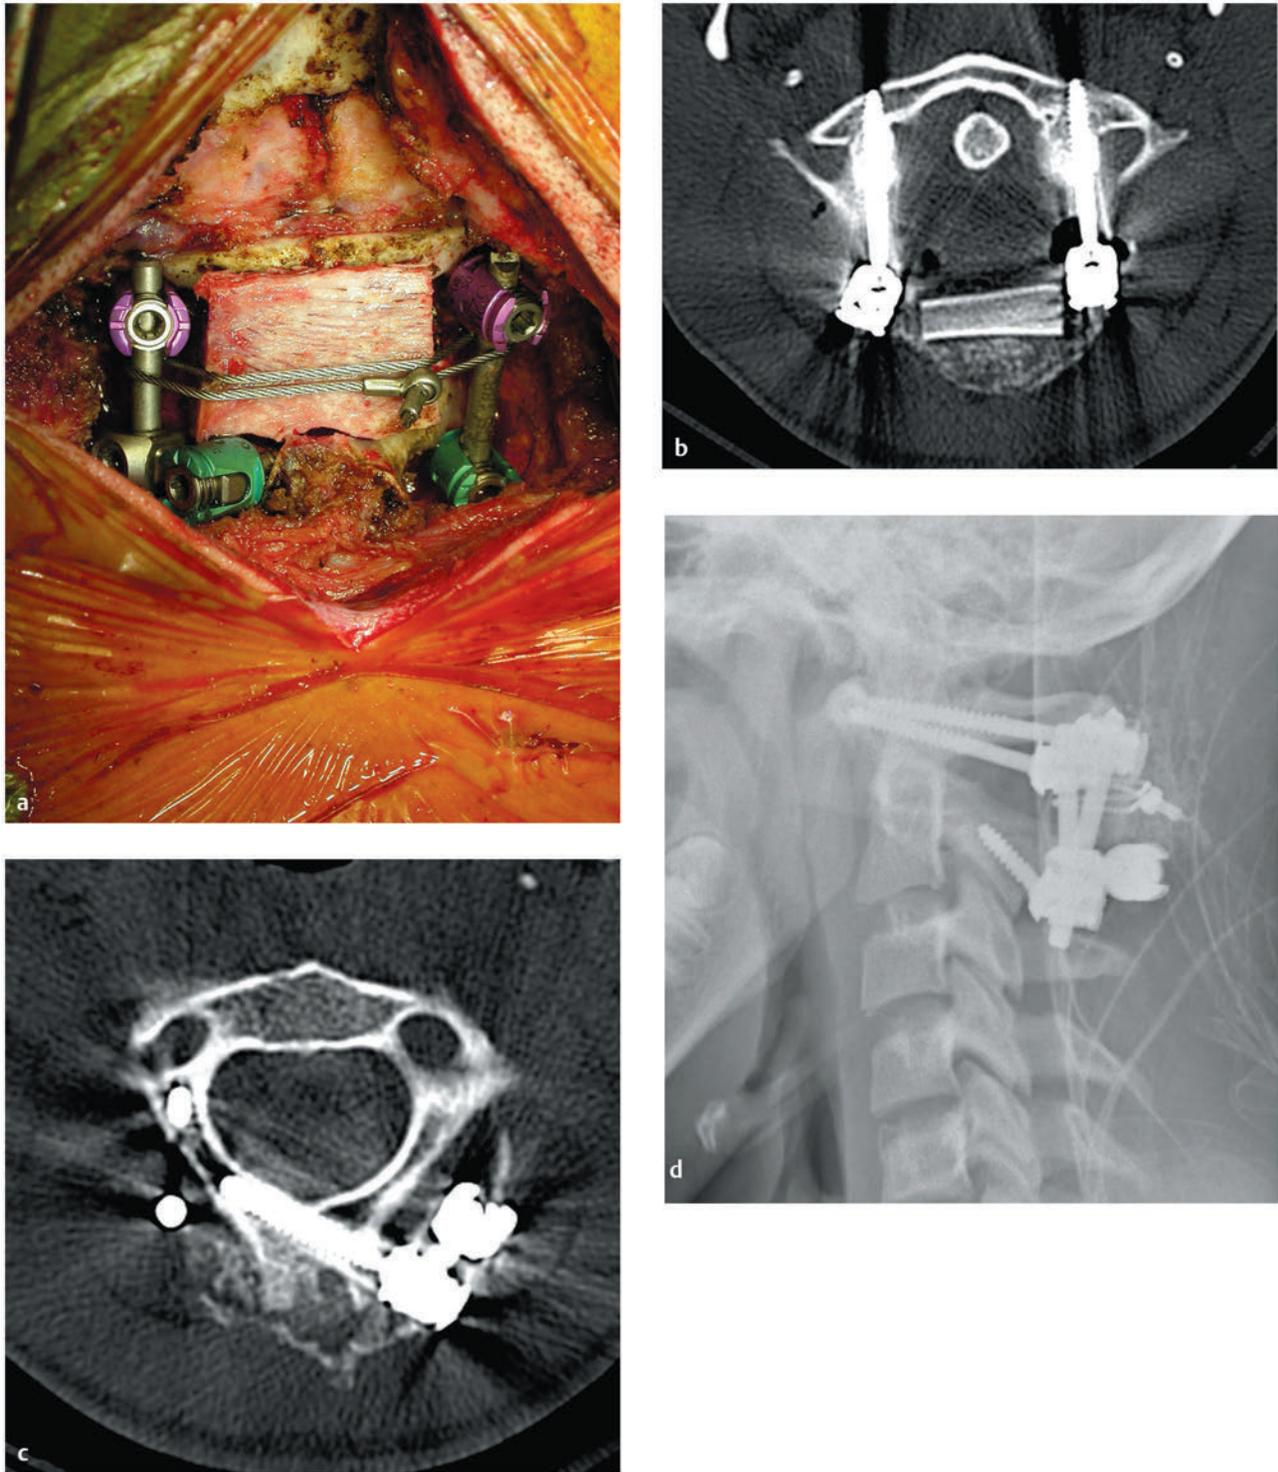

Fig. 61.4 Translational C1–2 subluxation. (a) Intraoperative photograph and (b,c) axial computed tomographic scans of a modified Goel-Harms type of fusion construct performed in the patient from ▶ Fig. 61.3 with traumatic C1–2 subluxation.^{63,64} Bilateral C1 lateral mass screws were placed and connected via metallic rods to the right C2 pars and left C2 laminar screws. An iliac crest bone graft was cabled in place between the posterior arch of C1 and the spinous process of C2. (d) Postoperative lateral radiograph of the fusion construct.

Atlantoaxial Rotatory Subluxation/ Atlantoaxial Rotatory Fixation

Injury Description

Atlantoaxial rotatory subluxation/atlas-odontoid fixation (AARS/AARF) represents a spectrum of abnormalities ranging from mild rotatory subluxation to absolute fixation with no motion (► Fig. 61.5, ► Fig. 61.6). Postulated mechanisms resulting in AARS/AARF include physiologic hypermobility of the C1–2 articulation, which can lead to rotatory subluxation during sudden and vigorous turning of the head, occasionally resulting in a true bony lock.³⁶ Other cases may be due to redundant synovial folds in children that become trapped in the C1–2 joint spaces at the extremes of rotation, jamming the articulation during counter-rotation; subsequent muscle spasm exacerbates the fixation.

Clinical Presentation

Only 30% of cases of AARS/AARF are traumatic in nature and usually result from only minor trauma.^{39,54} AARS/AARF has also been reported following inflammatory conditions of the head and neck, including pharyngitis, otitis media, retropharyngeal abscess (e.g., Grisel syndrome), and tumors.³⁸ Children with AARS/AARF classically present with neck pain and the neck maintained in lateral flexion with the chin rotated to the opposite side (“cock robin” deformity). The neck pain typically worsens with attempted rotation to the corrective side. Children with this injury usually have no neurologic deficits; however, patients may rarely present with C2 radiculopathy or myelopathy.⁵⁵ Although it has been reported, death directly attributable to AARS/AARF is exceedingly uncommon.³⁶

Radiographic Diagnosis

Plain radiographs and static CT are generally unreliable for the diagnosis of AARS/AARF and have been supplanted by dynamic (“three-position”) CT studies (► Fig. 61.5a,b). Nonetheless, complete cervical radiographs with flexion–extension studies should still be obtained in children with suspected AARS/AARF to rule out fractures and gross instability. Before the advent of CT, the Sudeck sign (deviation of the C2 spinous process toward the side of the chin tilt caused by a conscious effort of the child to realign the frontal visual axis coupled with involuntary counter-rotation of the subaxial spine) seen on anteroposterior plain films was pathognomonic for AARS/AARF.³⁶ Based on plain films, Field and Hawkins devised a classification scheme for AARS/AARF.⁵⁵ Type I is rotatory fixation without anterior or posterior shift of the atlas; it is the most common type in children and is also the most stable because the transverse ligament remains intact. Type II is rotatory subluxation with anterior shift of the atlas more than 3 mm but less than 5 mm; this type involves compromise of the transverse ligament and is therefore considered more dangerous. Type III is similar to type II, however, there is greater anterior shift (>5 mm). Type IV is rare and usually fatal, involving rotatory fixation with posterior shift of the atlas.

The relationship of C1 to C2 can be well visualized on dynamic CT, and CT is more accurate than plain films in diagnosing AARS/AARF.^{38,56} Lee and Pang developed a specific CT protocol wherein images are obtained with the patient’s head in certain positions to develop a C1–2 motion curve; deviation from the normal motion curve is then used to diagnose and determine the specific subtype of AARS/AARF.⁵⁷ Based on their data, AARS/AARF can be classified into several types and subtypes. Type I is a true bony lock, with a fixed C1–2 angle as the head

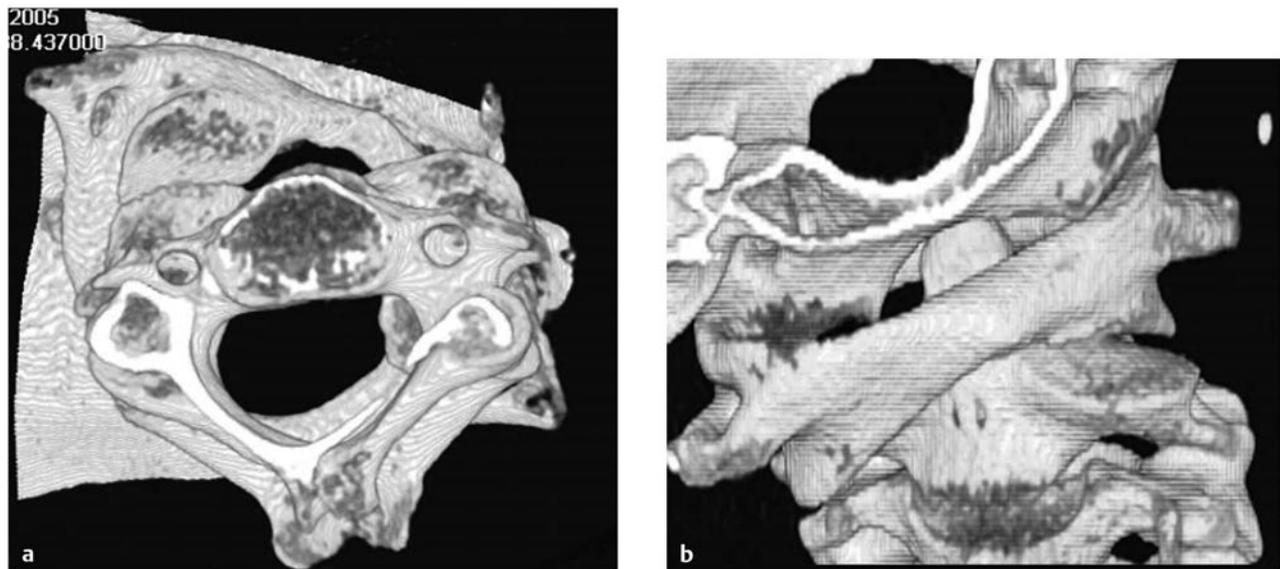

Fig. 61.5 Atlantoaxial rotatory subluxation (AARS). (a) Axial and (b) coronal three-dimensional reconstructed images of C1–2 in a 9-year-old girl with AARS that was refractory to conservative management. This patient ultimately required open reduction under general anesthesia with a posterior instrumented fusion.

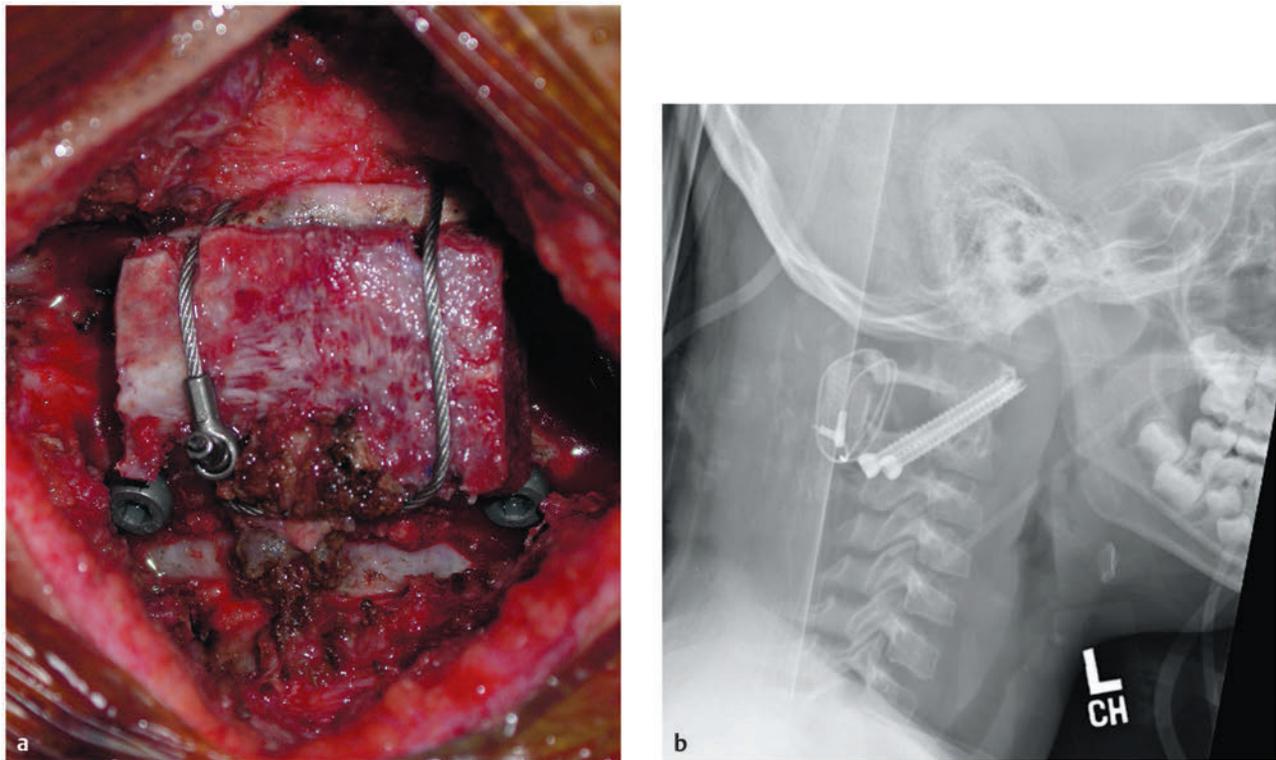

Fig. 61.6 Atlantoaxial rotatory subluxation (AARS). (a) Intraoperative photograph and (b) postoperative lateral radiograph of the fusion construct performed in the patient from ► Fig. 61.5 with refractory AARS. Following open reduction under general anesthesia, stabilization was achieved with bilateral C1–2 transarticular screws, and an iliac crest bone graft was cabled in Sonntag-Dickman fashion between the posterior arches of C1 and C2.⁶⁵

turns in the corrective direction. In type II, the C1–2 angle diminishes with corrective rotation; this type likely results from soft tissue interposition within the C1–2 joint, as opposed to a bony lock. Type II AARS/AARF is further subdivided into types IIA and IIB. In type IIA, the C1–2 angle never reaches 0 degrees because C1 never crosses to the other side of C2. This is the most common form of AARF. Conversely, in type IIB, C1 does cross to other side of C2, but only when C1 is at or less than 10 degrees. This suggests a pathologically sticky C1–2 articulation.

Treatment

The treatment of acute or subacute Field-Hawkins type I AARS/AARF generally consists of a combination of medical therapy (nonsteroidal anti-inflammatory drugs and muscle relaxants) and reduction via cervical traction.^{38,56,58} Following reduction, external immobilization for 4 to 6 weeks with a rigid collar is recommended. The duration of symptoms before treatment is a critical determinant of the response to conservative treatment. If treatment is not initiated within 1 month, the chances of restoring normal motion to the joint are much less than if treatment is begun acutely.³⁸ Recurrence of AARS/AARF should be treated with repeated reduction and halo immobilization. Failure of reduction or a second recurrence, which may indicate transverse ligament incompetence, should prompt consideration of open reduction and C1–2 fusion (► Fig. 61.6a,b).

Field-Hawkins types II and III should be considered inherently unstable because of injury to the transverse ligament and are most appropriately treated with open reduction and C1–2 fusion. Lee-Pang chronic type I (true bony lock) injuries are also unlikely to respond to conservative management. It is important to note that untreated atlantoaxial rotation can result in compensatory atlanto-occipital laxity and possible instability.^{38,59}

Odontoid Fractures

Injury Description

True odontoid fractures are rare in children (► Fig. 61.7). In children, translational C1–2 subluxation is most frequently the result of epiphysiolysis at the dentocentral synchondrosis, which is located slightly lower than the base of the dens within the rostral aspect of the C2 vertebral body and is not fused until 8 to 11 years of age. Most dentocentral synchondrosis fractures occur in children younger than 3 years of age.⁶⁰ These fractures tend to decompress the spinal cord and rarely lead to a neurologic deficit.

Clinical Presentation

The majority of children with fractures of the odontoid process present after severe falls or motor vehicle accidents, although

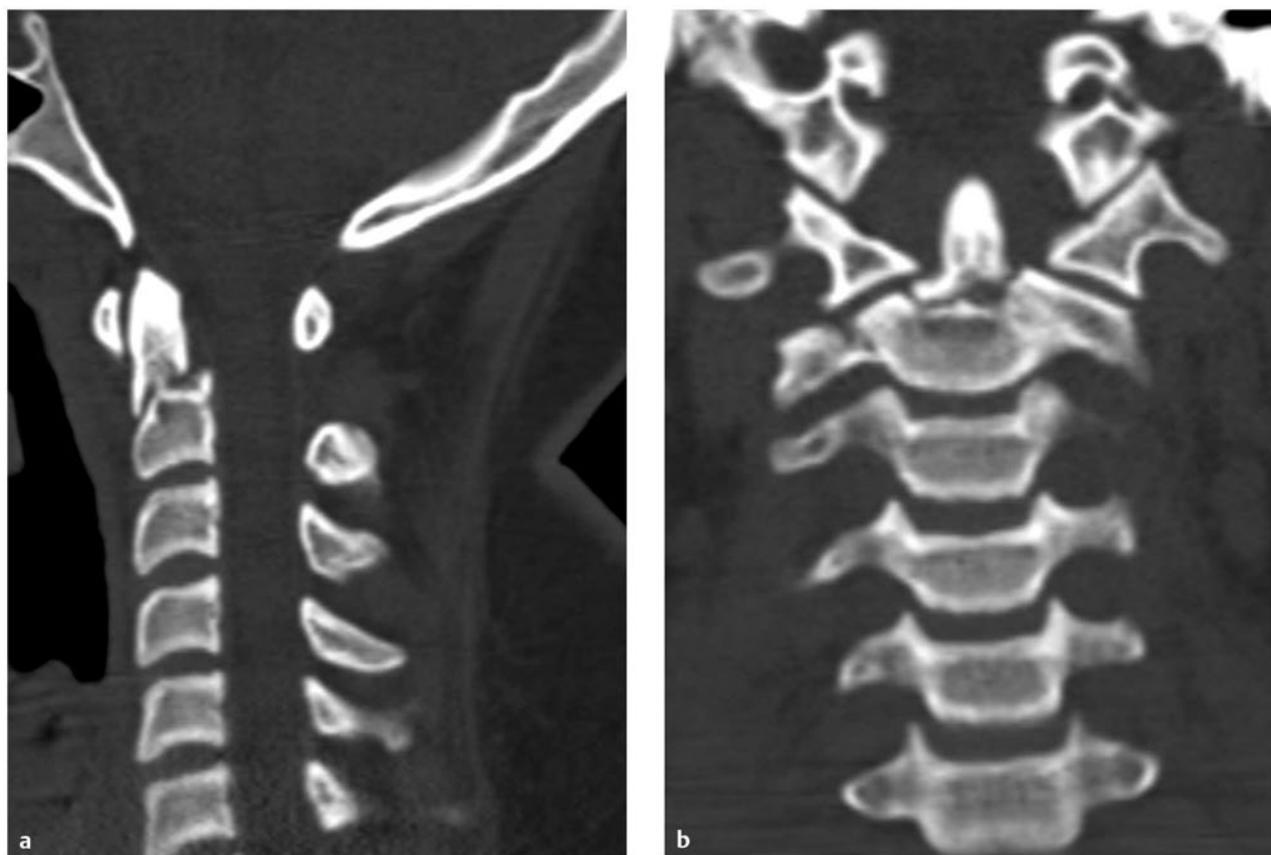

Fig. 61.7 Odontoid fracture. (a) Sagittal and (b) coronal computed tomographic scans demonstrating a type II odontoid fracture in an 18-year-old young man following a motor vehicle accident. Odontoid fractures in children are most commonly actually epiphysiolysis at the dentocentral synchondrosis (which is located slightly below the base of the dens in the rostral C2 body) rather than true odontoid fractures. The patient was successfully treated with halo ring immobilization.

some fractures may occur after only minor trauma. Neck pain is the most common complaint. Some patients may also be obtunded from concomitant head injury, given the high percentage of cervical injuries that are associated with head trauma.⁶¹ The majority of children who present with odontoid fractures are neurologically intact because cord injury at this level is often acutely fatal.

Radiographic Diagnosis

True odontoid or dentocentral synchondrosis fractures can easily be seen on lateral plain films. There is often anterior angulation or displacement of the rostral odontoid process (► Fig. 61.7a). The ADI is normal in isolated fractures. An abnormal ADI suggests concomitant disruption of the transverse ligament. In epiphysiolysis, CT may demonstrate an abnormally widened growth plate.

Treatment

There are few recommendations for the treatment of odontoid injuries in children. In a series of 35 children, Sherk et al reported that only 1 child with an odontoid injury required surgical fusion.⁴³ More recently, in a series of 13 children with odon-

toid fractures, 80% of those treated with halo immobilization for 10 to 18 weeks demonstrated a stable fusion. In general, children with odontoid fractures can be adequately treated with early external immobilization. C1–2 fusion is recommended in cases of failed fusion after immobilization or if the transverse ligament is disrupted.

Os Odontoideum

Injury Description

Os odontoideum was first described by Giacomini in 1886 and is a rare radiographic diagnosis defined as separation of an ossicle of bone from the odontoid process with no continuity to the body of the axis (► Fig. 61.8, ► Fig. 61.9, ► Fig. 61.10). Approximately 60% of patients present before 20 years of age, with a median age of 15 years. Although some authors have argued that os odontoideum is congenital, most now believe that it is an acquired lesion and represents a chronic nonunion from remote trauma. Functionally, os odontoideum is similar to a chronic type II odontoid process fracture, and most authors view it as unstable, with a risk for catastrophic injury to the upper cervical cord if left untreated.⁶²

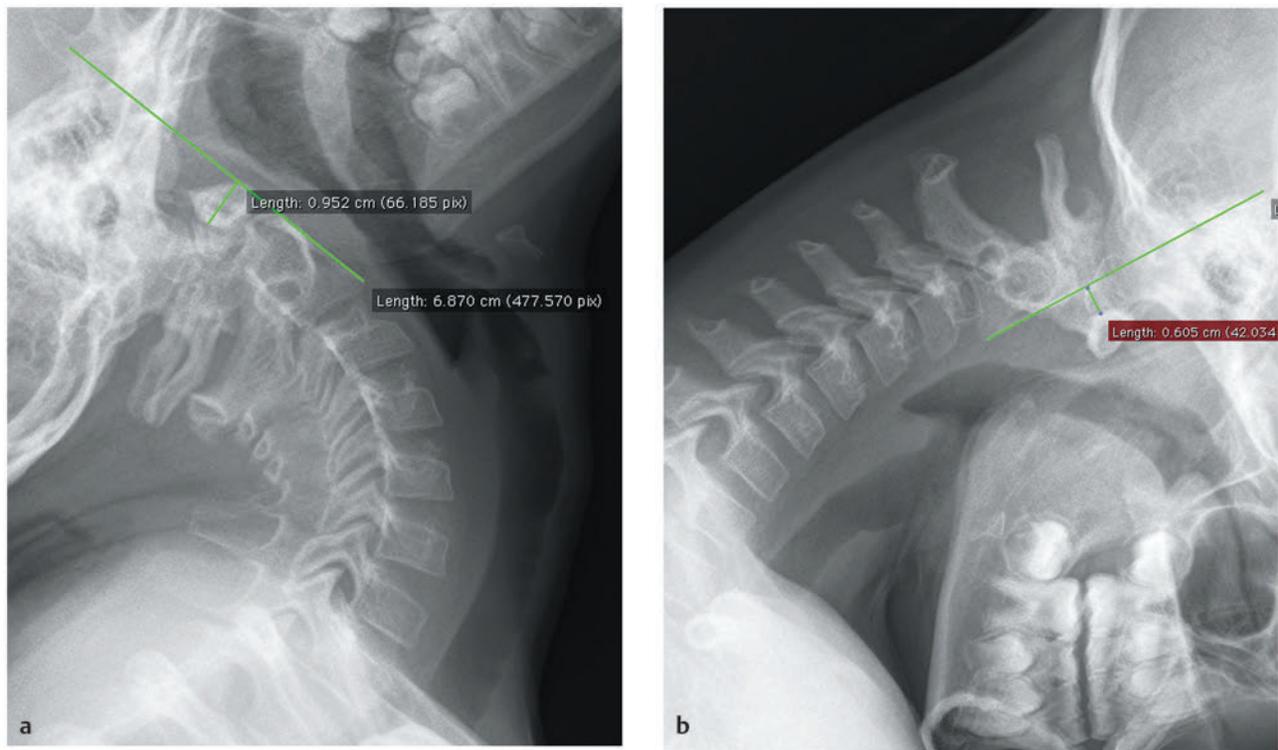

Fig. 61.8 Os odontoideum. Preoperative (a) extension and (b) flexion radiographs demonstrating gross instability with 15 mm of subluxation at C1–2 in a 9-year-old boy with os odontoideum who presented with vertebrobasilar insufficiency.

Clinical Presentation

The most common presenting symptom in patients with os odontoideum is neck pain, occurring in about two-thirds of patients. Approximately half of patients present following an instance of trauma, including falls, motor vehicle accidents, and sporting accidents. Neurologic symptoms on presentation may include myelopathy (23%) or transient paresthesias or quadriplegia (19%) following even relatively minor trauma.⁶² Headaches and symptoms suggestive of posterior circulation ischemia have also been reported (► Fig. 61.9c).

Radiographic Diagnosis

Os odontoideum can be diagnosed on lateral plain radiographs or CT scans demonstrating a well-corticated discontinuity between the odontoid peg and the body of the axis (► Fig. 61.8, ► Fig. 61.9, ► Fig. 61.10). The appearance is similar to that of a chronic type II odontoid fracture. The majority of patients demonstrate evidence of instability on flexion–extension radiographs (► Fig. 61.8a,b).⁶² MR imaging may demonstrate spinal cord edema in the C1–2 region.

Treatment

Most authors view os odontoideum as an unstable lesion with the potential for catastrophic cervical SCI from relatively minor

trauma even in asymptomatic patients. Treatment should include decompression (if necessary), reduction, and internal stabilization and fusion (► Fig. 61.10).⁶² This may be achieved through the use of transarticular screws or other C1–2 instrumentation (i.e., a Goel-Harms construct^{63,64}) in conjunction with a structural bone graft secured with cabling (e.g., the Dickman-Sonntag technique).⁶⁵

Hangman's (C2 Pars) Fracture

Injury Description

Hangman's fractures are rare in the pediatric population (► Fig. 61.11a–c). When a hangman's fracture does occur, it is most often due to a hyperextension mechanism, similar to that seen in adults. Classic causes include motor vehicle accidents, falls, diving accidents, and collisions during contact sports.

Clinical Presentation

Most children with C2 pars fractures present with neck pain. This fracture type typically results in widening of the spinal canal; therefore, neurologic deficits following a hangman's fracture are rare. Only a few cases of neurologic injury following this injury have been reported in children.^{66,67}

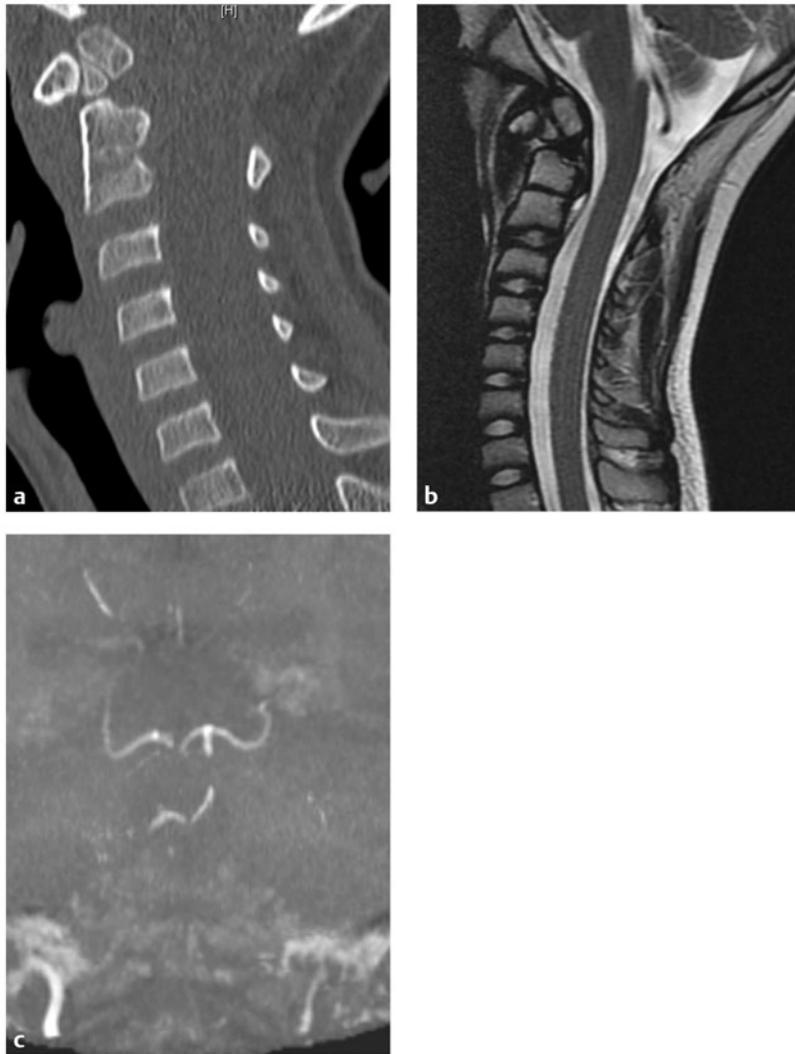

Fig. 61.9 Os odontoideum. Preoperative (a) sagittal computed tomographic and (b) sagittal magnetic resonance (MR) imaging of the same patient as in ▶ Fig. 61.8 clearly shows a well-corticated ossicle in the region of the dens in discontinuity with the remainder of the axis. (c) Preoperative MR angiogram from this patient demonstrating severe vertebral artery insufficiency from kinking of the vertebral arteries due to C1–2 instability.

Radiographic Diagnosis

The diagnosis of a hangman's fracture can be difficult in children because the neurocentral synchondrosis—the junction of the ventral and paired posterior ossification centers of the axis body—can mimic a fracture on oblique radiographs in patients younger than 7 years. Pseudo-subluxation at C2–3 may also be present in many children and can mimic true subluxation. When the diagnosis is in doubt on plain films, CT scans should be obtained through the region of interest.

Treatment

The treatment of C2 pars fractures is similar to that in adults.⁶⁸ If the body of the atlas is not significantly displaced on C3, immobilization in a rigid collar should be adequate. If there is anterior displacement greater than 3 mm, external immobilization in a halo vest or Minerva cast is more appropriate. Surgical fusion is rarely required and is generally reserved for cases in which external immobilization fails to result in healing of the fracture or in which there is evidence of significant associated ligamentous injury.

61.1.2 Subaxial Cervical Spine Injuries

Purely Ligamentous Injury (Subluxation without Fracture)

Injury Description

These injuries include trauma to the supporting ligaments and soft-tissue structures of the cervical spine below C2. They range from very mild to severe injuries that completely disrupt supporting structures, leading to gross spinal instability.

Clinical Presentation

Nearly all patients with purely ligamentous injuries of the subaxial cervical spine present with neck pain. Neurologic deficits, including radiculopathy, myelopathy, or both, may also be seen. Neck pain that persists for several weeks following trauma is unusual and should be investigated with radiologic studies.

Radiographic Diagnosis

Plain radiographs in a child with purely ligamentous injury of the subaxial cervical spine may range from normal to grossly

Fig. 61.10 Os odontoideum. Postoperative lateral radiograph of the fusion construct performed on the patient in ► Fig. 61.8 and ► Fig. 61.9. Following open reduction, stabilization was achieved with a Goel-Harms type of fusion construct,^{63,64} with bilateral C1 lateral mass and C2 pars screws and cabling of an iliac crest structural bone graft.

abnormal in appearance. Although static plain films may be normal, dynamic radiographs may unmask instability. The diagnostic criteria for determining instability in children with purely ligamentous injuries of the lower cervical spine are not well defined. White and Panjabi demonstrated that horizontal displacement of one vertebral body on another of more than 3.5 mm is consistent with significant ligamentous rupture in adults.^{42,69,70} The pediatric spine exhibits greater physiologic movement in the horizontal plane than does the adult spine. As such, displacement of up to 4.5 mm at a given segmental level may be considered normal and is termed *pseudosubluxation*, most commonly seen at C2–3 and C3–4.^{71,72} The following recommendations were developed by Pang and Sun to distinguish clinical instability from physiologic hypermobility in the subaxial cervical spine of children following trauma³⁶:

1. In children older than 8 to 9 years, the spine is developmentally similar to that of adults. Therefore, horizontal displacement of more than 3.5 mm should be considered unstable.
2. In children younger than 8 to 9 years, the physiologic mobility of the subaxial cervical spine is increased, particularly at C2–3 and C3–4. Horizontal displacement of more than 4.5 mm should be considered unstable.
3. In children younger than 8 to 9 years, if displacement between 3.5 to 4.5 mm is accompanied by prolonged muscle spasm, pain, neurologic findings, or other abnormalities (i.e., an avulsed spinous process or widened interspinous space), then clinical instability should be assumed.

In addition to horizontal displacement, the degree of kyphotic angulation following trauma can be used to determine whether a given injury is stable. White and Panjabi determined that the angle between adjacent vertebrae in normal adults is always less than 11 degrees and that kyphotic deformities with a larger angle should be considered unstable.^{42,69,70} In children, however, the developing spine is more elastic and predisposed to recoil. Therefore, following trauma, the angle of displacement demonstrated on lateral X-rays or CT may be much less than the maximal excursion at the time of impact, and a high degree of ligamentous disruption may accompany a minor kyphotic deformity on imaging. Most authors agree that a kyphotic angulation of more than 7 degrees likely represents a significant ligamentous injury that may predispose the developing spine to further kyphosis and instability.⁷³ Pang and Sun established the following algorithm to guide management in children with angular deformities of the subaxial cervical spine following trauma³⁶:

1. If a neutral lateral radiograph demonstrates more than 11 degrees of angulation, with or without neurologic deficits, overt instability should be assumed. Dynamic imaging should be deferred and surgical fusion considered.
2. If a neutral lateral radiograph shows between 7 and 11 degrees of angulation and there is a neurologic deficit, the injury is considered unstable. The assumption is that the displacement during the moment of impact must have been larger than that currently observed on imaging to result in myelopathy. Dynamic imaging should be deferred and surgical fusion considered.
3. If a neutral lateral radiograph demonstrates between 7 and 11 degrees of angulation and there is no neurologic deficit, then dynamic imaging should be obtained. If the angulation increases to 11 degrees or more, the injury is considered unstable and surgical fusion is appropriate. If the angulation is unchanged, dynamic imaging may be repeated in several days to eliminate confounding from muscle spasm. If repeated imaging demonstrates less than 11 degrees of angulation and the study is satisfactory, then external immobilization should be pursued until dynamic radiographs confirm healing of ligamentous structures.
4. If initial angulation on a neutral lateral radiograph is less than 7 degrees but the patient has severe pain and muscle spasm, external immobilization (i.e., a hard cervical collar) should be considered until satisfactory dynamic studies can be obtained to rule out instability.

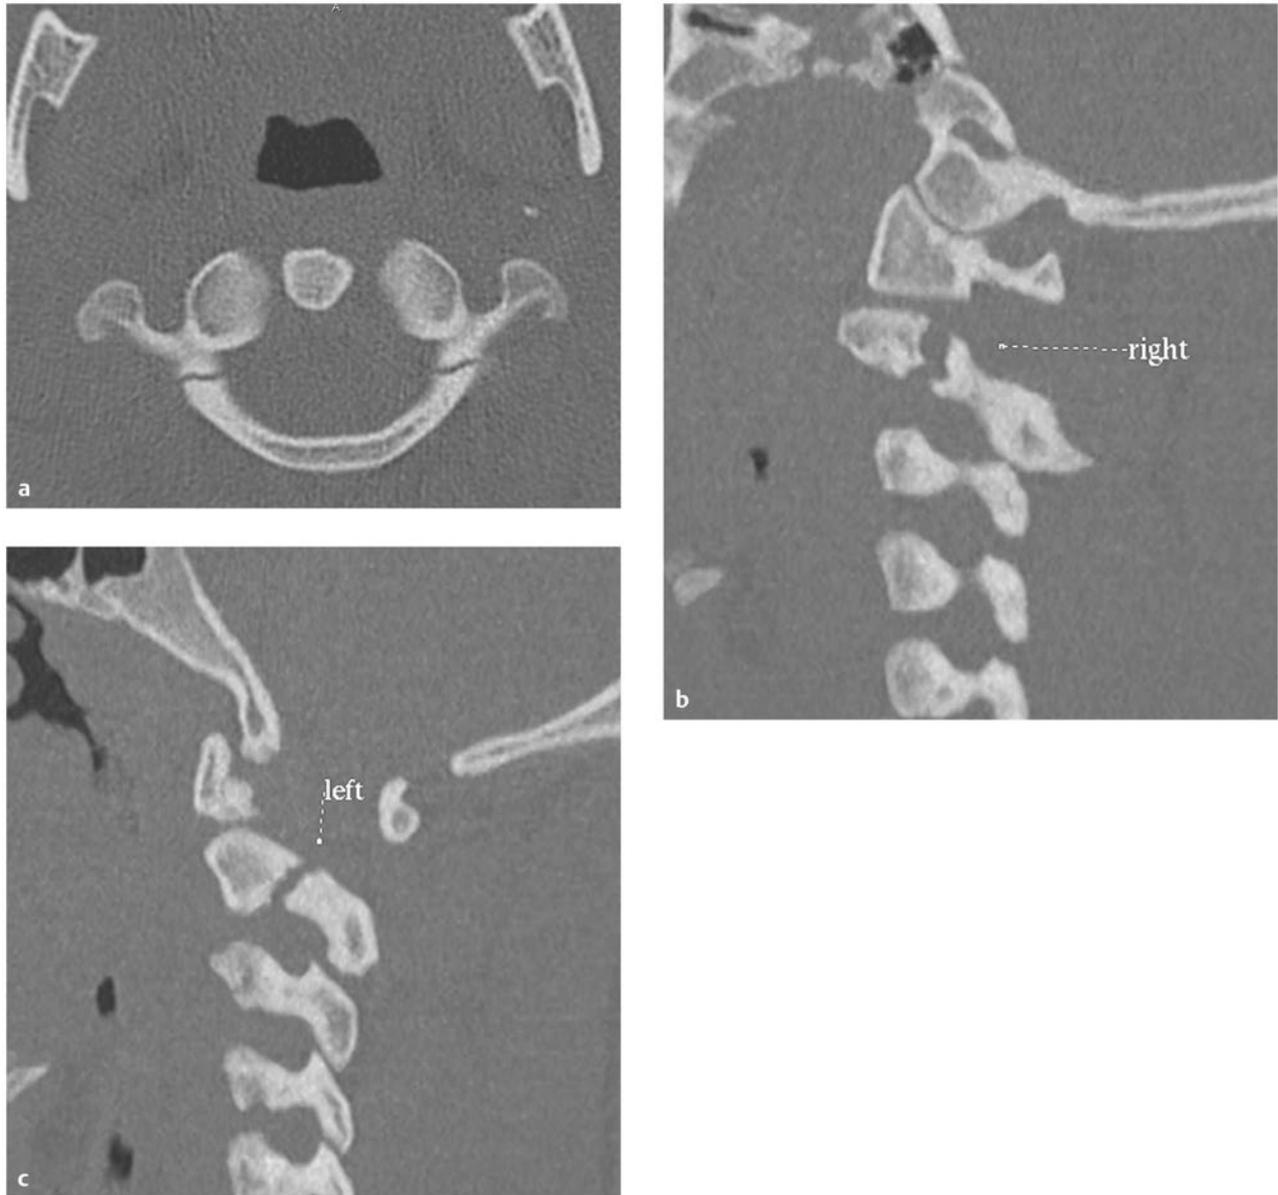

Fig. 61.11 Hangman's (C2 pars) fracture. (a) Axial and (b,c) parasagittal computed tomographic scans demonstrating a classic hangman's fracture with bilateral C2 pars involvement. Most fractures of this type can be treated with a rigid cervical collar if there is minimal displacement of the C2 vertebral body on C3. If there is more than 3 mm of displacement, external immobilization with a halo or Minerva brace should be strongly considered.

Evidence of instability in children with purely ligamentous injury of the subaxial cervical spine is often confined to a single level but may span two or more if the instability is particularly severe. CT scans are useful for confirming normal osseous anatomy and may also demonstrate indirect evidence of ligamentous injury, such as subluxation. MR imaging can be helpful to directly detect blood products in disrupted disk spaces or ligaments. On fat-suppressed T2-weighted MR imaging sequences obtained within 48 hours of trauma, high signal within the posterior interspinous and paraspinal soft tissues is suggestive of edema resulting from ligamentous and soft-tissue injury.

Treatment

Purely ligamentous injuries of the subaxial cervical spine that do not demonstrate gross instability on radiographic imaging can be managed conservatively with oral analgesics and, if necessary, a soft cervical orthosis for comfort. Most pain is associated with muscle spasm that usually resolves within 1 to 2 weeks after the injury. In children with more extensive ligamentous or soft-tissue injury that results in instability, operative reduction, internal fixation, and fusion should be considered. There are few series reporting on the management of purely ligamentous subaxial cervical spine injuries in children.

Finch and Barnes used primary operative stabilization to treat most children with this injury; however, they suggested that in at least some cases, external immobilization might have been sufficient.⁷⁴ Meanwhile, Pennecot et al treated minor ligamentous injuries with closed reduction and collar immobilization.⁷⁵ Despite this, however, 8 of 11 children in their series had injuries that ultimately required fusion. When operative management is undertaken, the operation to be performed depends on the specific pathology, as well as on surgeon and patient preference. Options include anterior approaches with allograft or autograft and plate/screw fixation, or posterior instrumented fusion. In cases of severe instability, instrumented fusion from combined anterior and posterior approaches may be considered to ensure proper alignment and long-term stability.

Osseous Anterior Column Injuries

Injury Description

Osseous anterior column injuries of the subaxial cervical spine (based on a two-column model) encompass all vertebral body

fractures from C3 to C7, including chip/teardrop, longitudinal, wedge compression, and burst fractures (► Fig. 61.12, ► Fig. 61.13). Fractures isolated to the anterior column are the most common fractures of the pediatric subaxial cervical spine.⁶⁰ The intervertebral disks of children have a higher collagen concentration, making them less predisposed to rupture when subjected to traumatic stresses. Instead, axial loading and compressive forces are transmitted to the annulus fibrosus and subsequently to adjacent vertebral bodies, which may then fracture. Burst fractures of the vertebral body may be categorized into one of five subtypes according to Denis: (1) type A, with both end plates involved; (2) type B, with only the superior end plate involved; (3) type C, with involvement of the inferior end plate only; (4) type D, which exhibits burst-rotation; and (5) type E, with burst-lateral flexion.⁷⁶

Clinical Presentation

Like those with other subaxial cervical injuries, most patients with osseous anterior column injuries present with neck pain. Some patients may be asymptomatic. The majority of these

Fig. 61.12 C7 burst fracture. (a) Sagittal computed tomographic scan and (b) magnetic resonance image demonstrating an unstable C7 burst fracture with spinal cord compression in a 17-year-old boy presenting with upper extremity paresthesias and numbness following a snowboarding accident. Also seen is a stable C5 anterior compression fracture with minimal angulation and loss of body height.

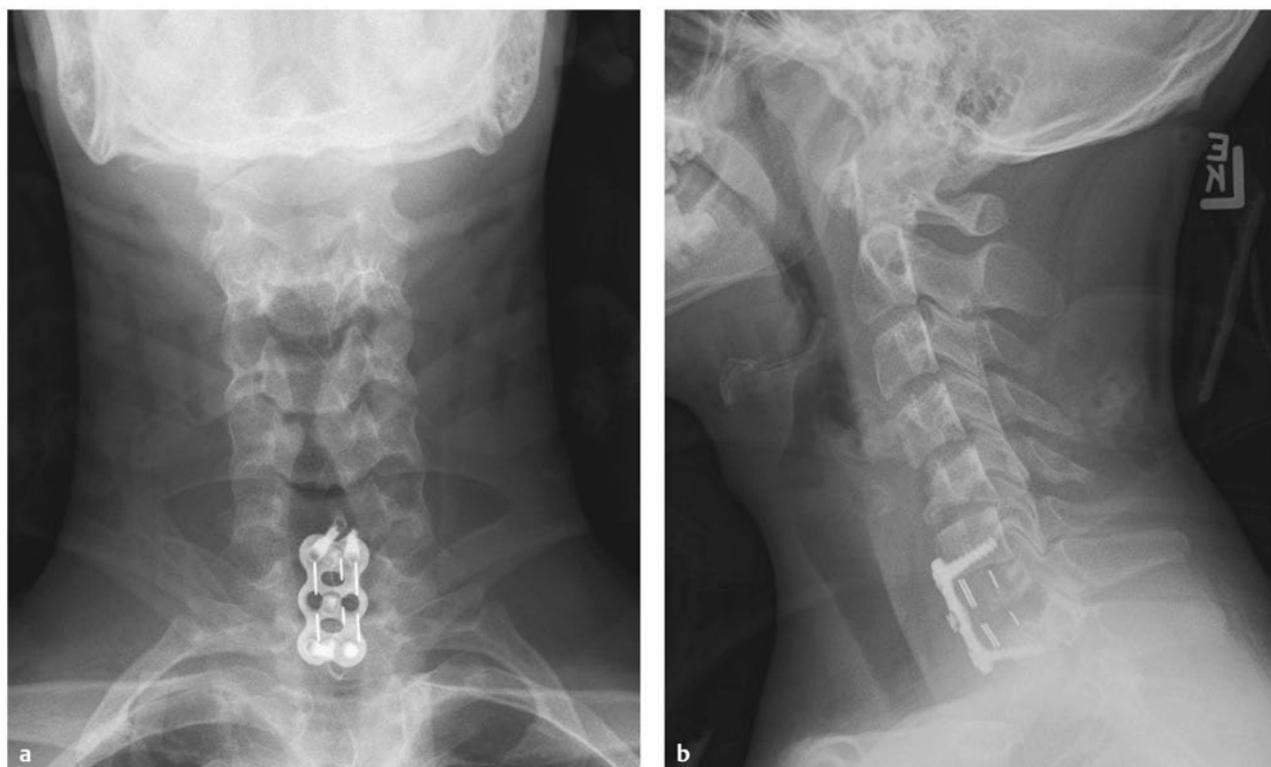

Fig. 61.13 C7 burst fracture. Postoperative (a) anteroposterior and (b) lateral radiographs of the patient in ▶ Fig. 61.12 demonstrating decompression via an anterior C7 corpectomy with placement of a synthetic interbody graft and anterior plating from C6 to C8.

injuries are discovered on screening lateral radiographs during the initial trauma evaluation when the patient reaches the hospital. If there is retropulsion of bone fragments into the spinal canal, patients may present with either myelopathy or radiculopathy. Higher cervical injuries, which are more frequent in the pediatric population, are more likely to result in injury to the spinal cord.

Radiographic Diagnosis

Most bony injuries to the anterior column of the subaxial cervical spine are visualized on plain radiographs. They may result in decreased vertebral body height, increased interpedicular distance, or splaying of the posterior facet joints. CT should be obtained if abnormalities on plain radiographs are not seen and suspicion for an injury is high (▶ Fig. 61.12a). MR imaging should be considered if the mechanism of injury is severe enough or the patient's examination is concerning for spinal cord or nerve root compression (▶ Fig. 61.12b). The utility of MRI has been demonstrated in identifying soft-tissue injury, acute disk herniation, and longitudinal ligament disruption, all of which may influence operative plans.⁷⁷ MR imaging is also valuable for detecting spinal cord contusions or infarctions in the presence of minor or remote fracture or in the absence of fracture.⁷⁸ In a study of high-risk patients with multiple injuries, plain films were 60% sensitive and 100% specific in detecting anterior column cervical injuries. CT was 90% sensitive and 100% specific in the same population.⁷⁹ This suggests the conclusion

that CT is valuable and should not be deferred in high-risk patients when subaxial cervical spine injury is suspected.

Treatment

The majority of osseous anterior column injuries in the subaxial cervical spine are stable fractures and heal in 4 to 6 weeks with conservative treatment. Immobilization with a rigid cervical collar is recommended for at least 2 to 4 weeks, with follow-up dynamic radiographs to confirm stability and rule out deformity.⁶⁰ Patients with significant kyphotic deformities or unstable injuries (burst fracture with spinal cord compromise and fractures associated with significant ligamentous disruption) should be managed surgically. For most significant osseous anterior column injuries the surgical treatment involves anterior cervical corpectomy and fusion with plating (▶ Fig. 61.13a,b).

Osseous Posterior Column Injuries

Injury Description

Injuries to the bony elements of the posterior column of the subaxial cervical spine encompass several types of fractures, including those to the facets, lateral masses, laminae, and spinous processes (clay shoveler's fracture). Also included in this category are jumped and perched facets, which may occur in conjunction with facet fractures. Isolated osseous posterior column injuries are rare in children and most often occur in

combination with ligamentous injury. Unilateral and bilateral facet dislocations have been reported in some series to be the second most common injury to the pediatric subaxial cervical spine.⁶⁰

Clinical Presentation

Posterior column injuries of the pediatric subaxial spine most often result from hyperextension, distraction, or rotation shear mechanisms.⁷⁶ Lamina and spinous process fractures are most often caused by hyperextension. Jumped and perched facets result from a combination flexion–distraction force, whereas rotation–compression forces tend to cause facet fractures.

The single most common presenting symptom is neck pain. Unilateral facet injury should be suspected when neck pain is accompanied by an isolated nerve root finding. Radiculopathy and myelopathy are not uncommon sequelae of osseous posterior column injuries in children.

Radiographic Diagnosis

Plain radiographs are usually sufficient to diagnose jumped or perched facets and spinous process fractures. Subluxation of more than 50% of the vertebral body width on lateral plain radiographs is almost pathognomonic for bilateral jumped facets.⁶⁰ Other osseous posterior column injuries may be quite difficult to discern without the addition of CT. MR imaging is useful for determining the degree of associated ligamentous injury and evaluating for underlying SCI or compression. MRI should be obtained if a child presents with neurologic findings or if plain radiography or CT demonstrates evidence of instability.

Treatment

The appropriate treatment of osseous posterior column injuries of the subaxial cervical spine is guided by a determination of whether the injury is stable or unstable. Stable bony injuries may be treated with a cervical collar for comfort. For grossly unstable injuries, such as bilateral jumped facets, treatment should involve reduction and surgical fusion. If the patient is alert and has a reliable neurologic examination to be followed, closed reduction may be attempted manually or with tong traction. If closed reduction fails, open reduction during the fusion operation should be performed. Alternatively, one may forgo attempts at closed reduction and proceed directly to open reduction and fusion, particularly when an injury is subacute or chronic. In these cases, the presence of significant muscle spasm and taught ligaments often makes achieving a successful closed reduction unlikely. It is prudent to obtain an MRI study before reduction, if possible, to assess for an asymptomatic herniated intervertebral disk or impending spinal cord compression that may be exacerbated during reduction maneuvers.

For some injuries, the determination of stability is less clear. Examples include unilateral perched or jumped facets. If malalignment of the facets can be corrected with closed reduction, the injury may heal over time with external immobilization only. In these instances, it is critical to take into account the amount of associated ligamentous injury and whether the anterior column is additionally involved. If conservative treatment is pursued, flexion–extension radiographs should be

obtained 2 to 3 months following trauma to assess for maintenance of stability. Persistent neck pain despite appropriate reduction and external stabilization should raise the suspicion of significant concomitant ligamentous injury and argues for surgical fusion.

Combined Anterior and Posterior Column Injuries

Injury Description

Combined anterior and posterior column injuries involve disruption of all supporting structures (i.e., bone, ligaments, and soft tissues) of the subaxial cervical spine at one or more levels (► Fig. 61.14, ► Fig. 61.15). Fracture–dislocation injuries fall into this category. They are rare in the pediatric age group, result from severe trauma, and are highly unstable.

Clinical Presentation

Most children with combined anterior and posterior column injuries present following severe trauma with a high-energy mechanism. A large percentage of these patients have evidence of a neurologic deficit from SCI.⁶⁰

Radiographic Diagnosis

Because of disruption of all supporting elements of the spinal column, plain radiographs will typically demonstrate misalignment of the cervical spine with distraction of the interspace at the level of injury.⁶⁰ CT is helpful to delineate fractures associated with the injury complex (► Fig. 61.14a,b). MRI is useful in assessing the degree of ligamentous and soft-tissue injury, as well as in identifying compressive lesions (e.g., herniated fragments from intervertebral disk rupture) and SCI (► Fig. 61.14b).

Treatment

Combined anterior and posterior injuries, including fracture–dislocations, are inherently unstable and must undergo surgical stabilization. Either an anterior or posterior approach, or both, may accomplish this, as long as the primary goals of spinal cord decompression and sufficient spinal column stability are accomplished. The choice of which approach to pursue depends on the specific pathology of the injury (e.g., the presence of an anterior compressive lesion) and surgeon preference. Combined anterior and posterior fusion is recommended when gross instability is evident to prevent hardware failure and avoid the necessity of a postoperative halo orthosis (► Fig. 61.15a,b). Surgical treatment should be performed as soon as medically feasible following the injury, generally within the first several days.

61.1.3 Thoracic and Lumbar Spine Injuries

Traumatic injuries to the thoracic and lumbar spinal column in children are significantly less common than injuries to the cervical spine. In the United States, motor vehicle accidents are the most common cause of thoracic and lumbar spine

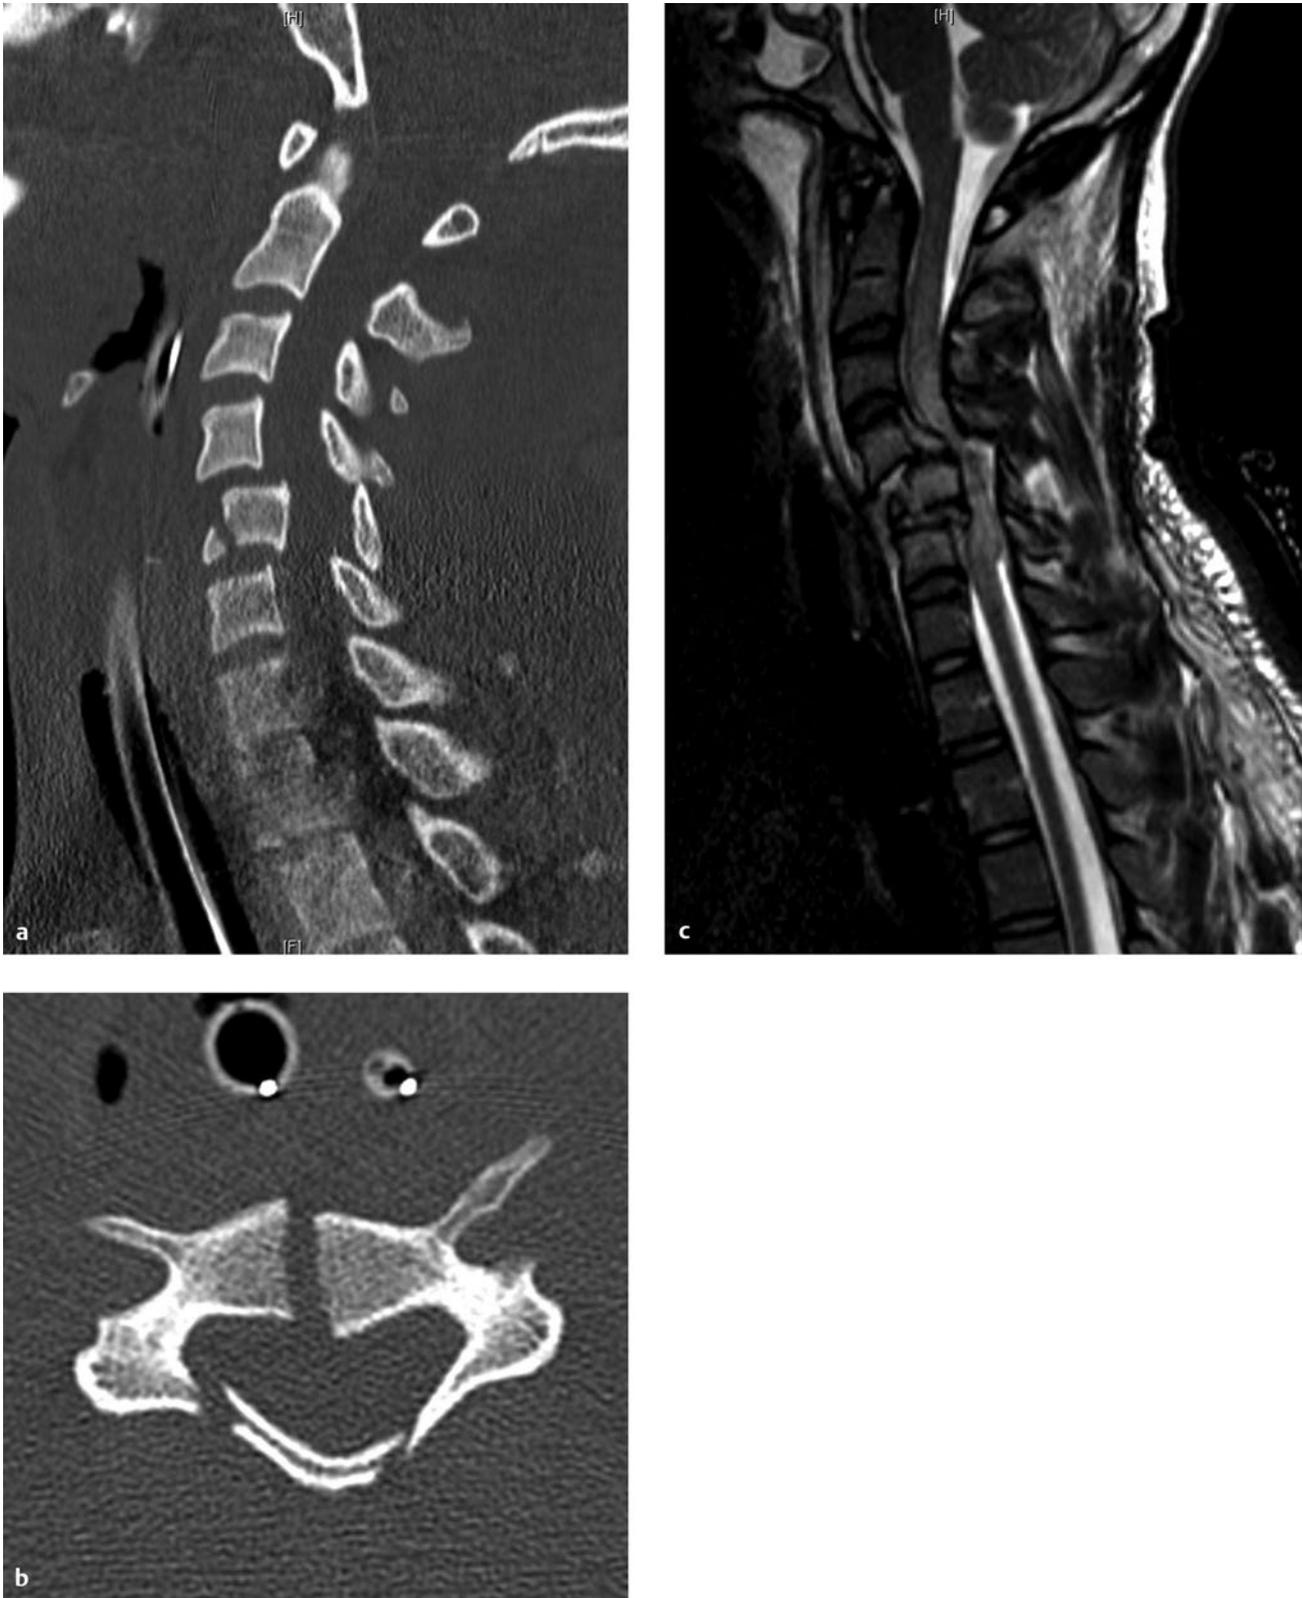

Fig. 61.14 Cervical fracture–dislocation. (a,b) Sagittal and axial computed tomographic scans and (c) sagittal magnetic resonance (MR) image of an 18-year-old boy with fracture–dislocation at C5 and a complete spinal cord injury following a motor vehicle accident. This injury involves disruption of the osseous and ligamentous structures of the anterior and posterior columns of the cervical spine, resulting in gross instability. Note the displacement of the C4 vertebral body on C5 and the jumped facets at the level of injury. The MR image demonstrates disruption of the anterior and posterior longitudinal ligaments and intervertebral disks, as well as extensive soft tissue and spinal cord edema. The patient was kept in cervical traction to maintain alignment until surgical decompression and stabilization were performed.

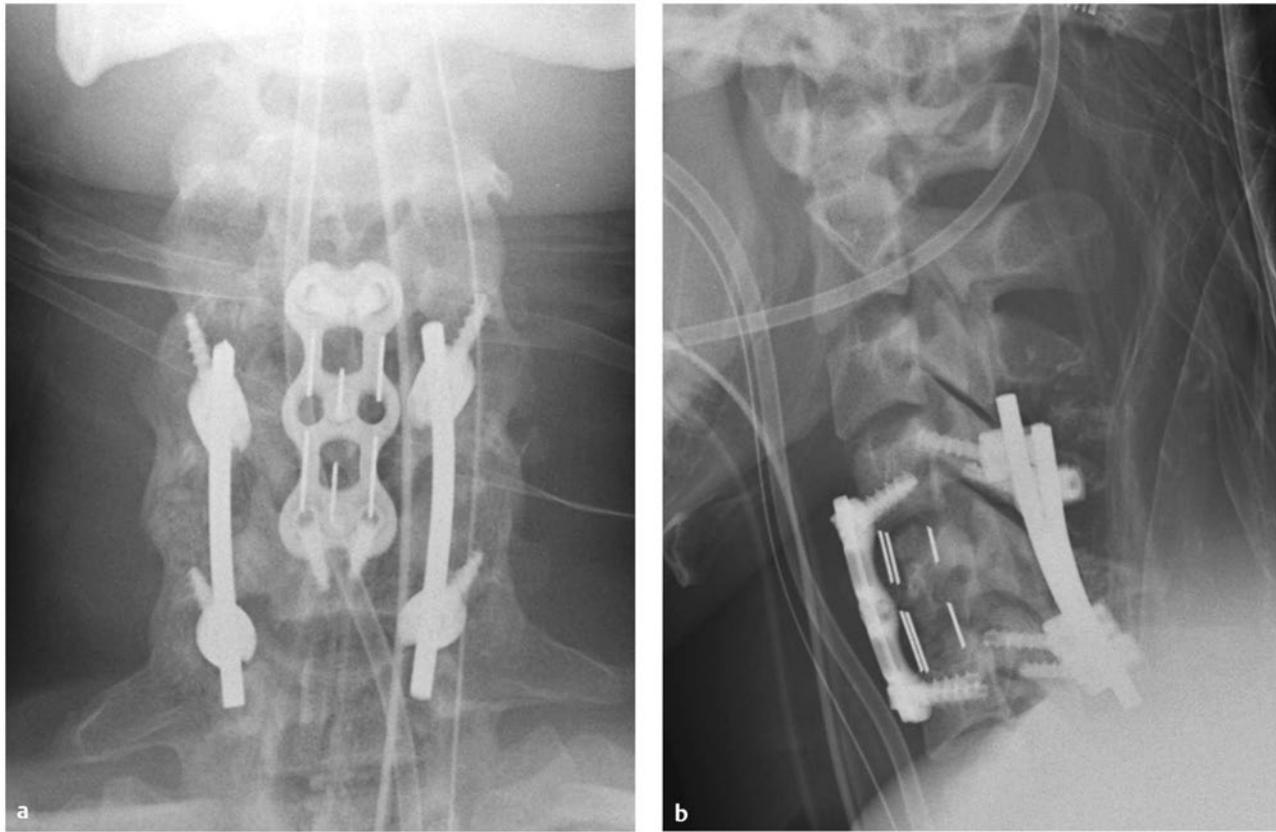

Fig. 61.15 Cervical fracture–dislocation. Postoperative (a) anteroposterior and (b) lateral radiographs of the patient in ▶ Fig. 61.14 demonstrating a combined anterior and posterior approach for decompression, reduction, and stabilization of his cervical fracture–dislocation. The initial stage consisted of a C5 corpectomy, reduction, placement of a synthetic interbody graft, and anterior plating from C4 to C6. This was followed by posterior segmental instrumentation and fusion from C4 to C6.

trauma in all pediatric age groups. Other common causes include pedestrian-versus-vehicle accidents and falls.⁸⁰ Similar injury types are commonly encountered in both the thoracic and lumbar spine in children, including compression (anterior or wedge) fractures, burst fractures, flexion–distraction injuries (Chance fractures), fracture–dislocation injuries, and apophyseal ring fractures.

Isolated thoracic spinal column trauma is quite rare because most flexion–extension within the spinal column occurs at the cervical and lumbar regions, making those regions more susceptible to injury. Osenbach and Menezes documented thoracic injury in only 13% of cases of children with spinal column injury or SCI without radiographic abnormality (SCIWORA),⁸¹ and Hadley et al reported that in a series of 122 children with spinal column trauma, only 11 (9%) had a purely thoracic spine injury.³¹ Thoracic spinal column injuries are most commonly compression or burst fractures. Mechanisms of injury include excessive axial loading and flexion forces from high-velocity impacts.

Lumbar spinal column injuries in children are most commonly caused by a flexion–extension mechanism and are frequently associated with lap seat belt use in the absence of a shoulder strap or harness. Flexion–distraction (Chance fracture), fracture–dislocation, and apophyseal injuries are the most common injury types in this region. Fractures are less

common in the lumbar spine than in the thoracic spine. When they do occur, older children are more likely to be affected.⁸²

Compression (Anterior Wedge) Fracture

Injury Description

Compression fractures of the anterior column are the most common type of fracture in the pediatric thoracic spine (▶ Fig. 61.16a,b). They are most frequently caused by a combination of flexion with axial loading and often affect multiple levels, occasionally with skipped, intervening normal levels.⁸³ Therefore, when one fracture is identified, additional compression fractures should be assumed to be present until it is proved otherwise. Like burst fractures, these fractures are more common in older children and adolescents.⁸⁴ Compression fractures are typically stable fractures because they involve only the anterior column (based on a three-column model of the thoracolumbar spine). The development of kyphosis or scoliosis in the year following a thoracic fracture is not uncommon; however, it is unclear whether the majority of these deformities are stable or increase in adulthood and become clinically relevant.⁸⁵ Persistent kyphotic deformity resulting from compression fractures is particularly uncommon in young children given continued bone growth and remodeling in this age group.⁸³

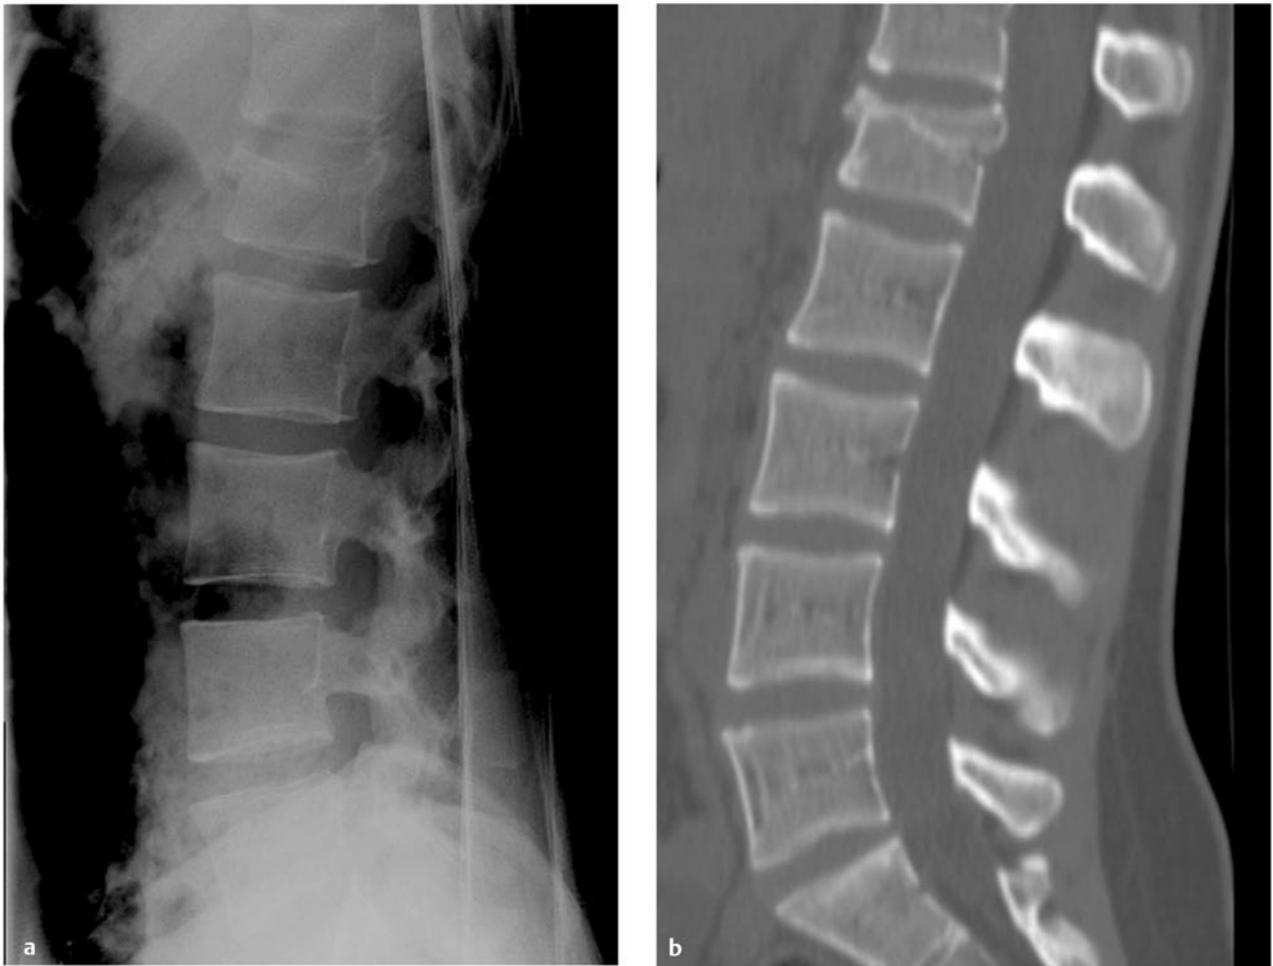

Fig. 61.16 L1 compression (anterior wedge) fracture. (a) Lateral radiograph and (b) sagittal computed tomographic scan demonstrating a nonoperative compression fracture of L1 in a neurologically intact young girl. Note the lack of significant angulation or retropulsed bone fragments. Thoracolumbar compression fractures can often be treated conservatively. External immobilization may aid in pain control and prevent the development of deformity during fracture healing and remodeling.

Clinical Presentation

The most common acute presentation of a child with a compression fracture of the thoracolumbar spine is localized axial back pain. Neurological deficit is rare given that only the anterior column is involved. Some children may present in a delayed fashion with pain or, less commonly, neurological deficit from progressive deformity.

Radiographic Diagnosis

The majority of thoracolumbar compression fractures can be adequately diagnosed and assessed with upright anteroposterior and lateral plain radiographs that demonstrate anterior wedging of the affected vertebral body (► Fig. 61.16a). Given the high incidence of multiple and skipped fractures, imaging of the entire spine should be routinely obtained when a compression

fracture is suspected. Kyphotic deformity may be present if multiple levels are affected. CT should be reserved for cases in which operative intervention is being considered. MRI should be performed in the exceedingly rare instance of an associated neurologic deficit.

Treatment

Because compression fractures of the anterior column of the thoracolumbar spine are stable injuries, the majority of patients should be treated conservatively with external immobilization in a thoracolumbar orthosis. Bracing may aid in pain control and prevent the development of kyphotic or scoliotic deformities during healing and remodeling of the fracture. Progressive kyphosis is more common in children with multiple compression fractures. In these children or others who develop significant deformities with persistent pain or neurologic deficit,

operative intervention, including instrumented fusion, may be appropriate.

Burst Fracture

Injury Description

Burst fractures of the thoracolumbar spine are caused by excessive axial loading and compromise of both the anterior and middle columns (► Fig. 61.17a–c). Like compression fractures, burst fractures are more common in older children and adolescents.⁸⁴ Retropulsion of bone fragments into the spinal canal may result in neurologic deficits. The risk for neurologic injury

has been shown to be more significantly associated with the level of injury than with the degree of canal compromise.⁸⁶ Thoracic burst fractures pose the greatest risk in this regard. Burst fractures may be either stable or unstable, generally depending on the degree of associated posterior ligamentous injury.

Clinical Presentation

Children and adolescents with thoracolumbar burst fractures most commonly present with localized axial back pain. Neurologic deficit, including radiculopathy from nerve root compression or myelopathy from cord compression, is much more

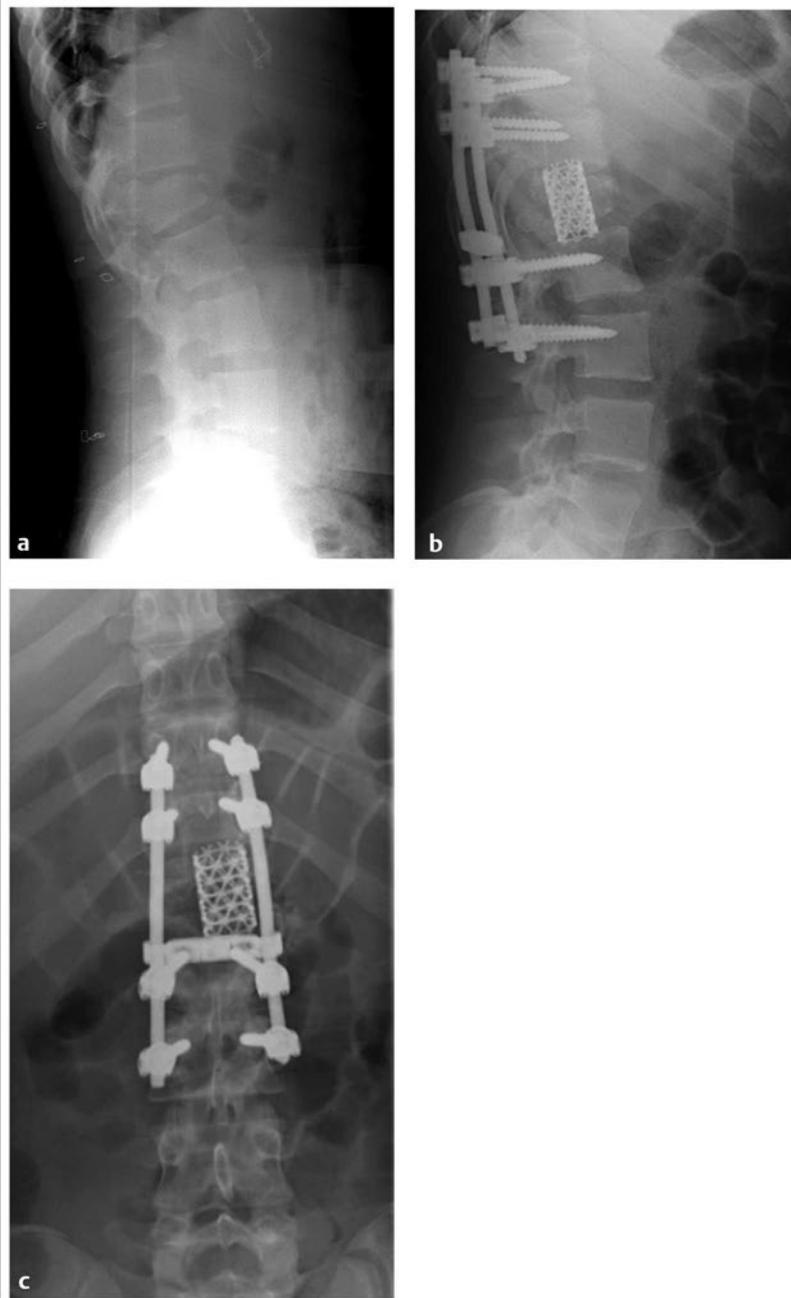

Fig. 61.17 L1 burst fracture. (a) Lateral radiograph demonstrating an unstable burst fracture of L1 in a 16-year-old girl who presented with an incomplete spinal cord injury following an all-terrain vehicle accident. The patient underwent decompression and stabilization through a posterior approach. Postoperative (b) lateral and (c) anteroposterior radiographs demonstrate an L1 corpectomy, placement of a metallic interbody cage, and placement of posterior segmental instrumentation and fusion from T11 to L3.

common than with compression fractures because of involvement of the posterior vertebral body and the potential for retro-pulsion of bone fragments into the spinal canal.

Radiographic Diagnosis

Plain anteroposterior and lateral radiographs are usually diagnostic for burst fractures, demonstrating involvement of both the anterior and middle columns of the thoracolumbar spine and associated loss of vertebral body height (► Fig. 61.18a). Retropulsed bone fragments may be observed. As with compression fractures, injury to multiple levels is not uncommon, and the entire spine should be screened with plain radiographs when a burst fracture is identified. CT is useful in these injuries to more accurately define the amount of vertebral body height loss, degree of kyphosis, and degree of canal compromise. MR imaging in the acute setting is valuable to further elucidate the degree of spinal cord or nerve root compression and assess the amount of associated posterior ligamentous injury, which aids in the differentiation between stable and unstable burst fractures.

Treatment

Children with no neurologic deficit and a stable burst fracture may be treated conservatively with external immobilization in a thoracolumbar orthosis. Children with unstable fractures or those with neurologic deficit from nerve root or cord

compression should undergo operative management. The goals of surgery should be decompression of the affected neural elements, fracture reduction, and stabilization of the spinal column.⁸⁷ Options include anterior decompression, posterior decompression, structural interbody graft placement, anterior fusion, posterior fusion, or a combination of the above, as determined by the expertise of the individual surgeon. Dorsal and dorsolateral approaches to the vertebral body (i.e., transpedicular, costotransversectomy, and lateral extracavitary approaches) may mitigate the risks associated with anterior approaches (► Fig. 61.17b,c). Few series have reported on the long-term outcomes of operative intervention in pediatric patients with thoracolumbar burst fractures. Lalonde et al. however, did publish a small series of 11 children with this injury; 6 patients were treated nonoperatively with external bracing, and 5 patients with more severe fractures underwent surgical stabilization.⁸⁸ In this series, the children who were treated surgically were less likely to develop long-term kyphotic progression than those who were treated nonoperatively.

Flexion–Distraction Injury (Chance Fracture)

Injury Description

Chance fractures most frequently occur in the upper lumbar region and involve a horizontal fracture through all three columns of the spine, including the vertebral body, pedicles, and laminae. These injuries are classically associated with the use

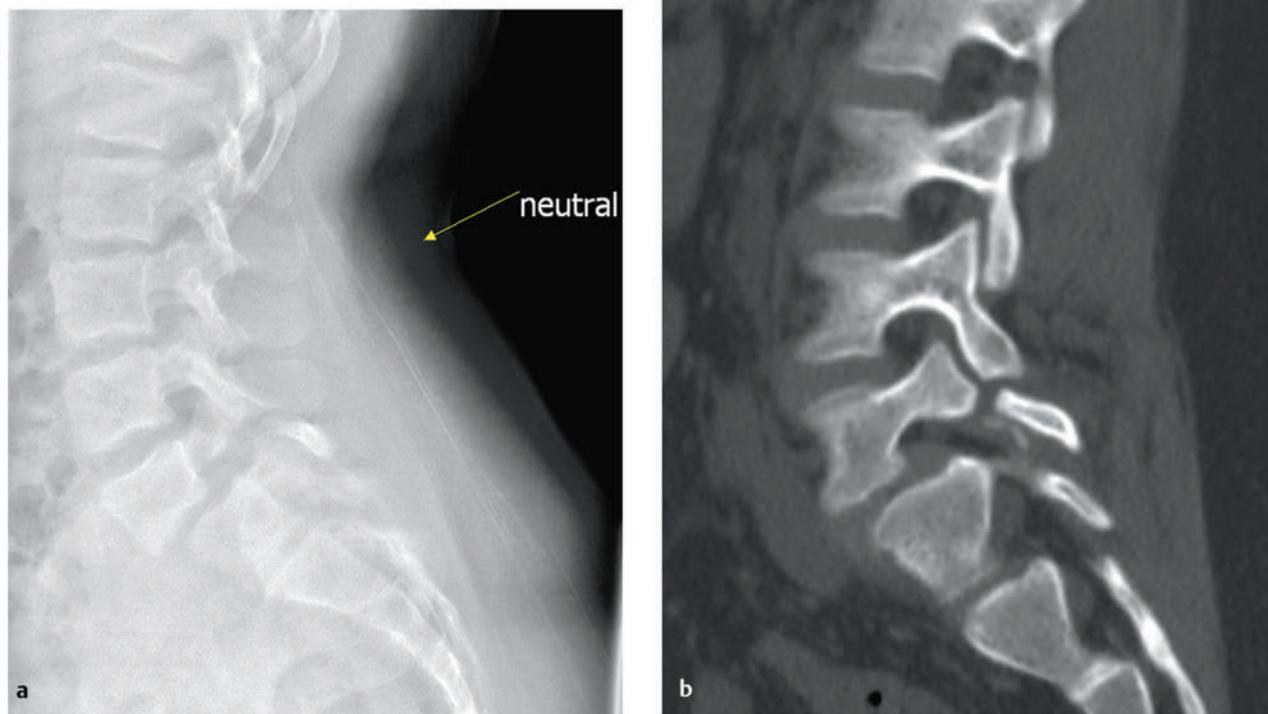

Fig. 61.18 Spondylolysis with spondylolisthesis. (a) Lateral radiograph and (b) sagittal computed tomographic scan demonstrating a chronic post-traumatic L5 pars fracture (spondylolysis) in a young girl with a Meyerding grade 2 anterolisthesis of L5 on S1.

of a lap seat belt without a shoulder harness, although they can be seen in both unrestrained and properly restrained children involved in moderate- to high-speed motor vehicle accidents.^{31,84} When a lap seat belt without a shoulder harness is used in the setting of a moderate- to high-speed decelerating force, the seat belt–abdomen interface becomes the new axis of rotation. This transfers distracting forces to the entire spinal column. The most common single level involved is L2, although flexion–distraction injuries also occur not infrequently at the thoracolumbar junction and in the lower lumbar spine.⁸⁹ Associated intra-abdominal injuries have been reported in as many as 50% of children with flexion–distraction injuries.⁹⁰

Clinical Presentation

The most common presenting symptom is back pain. Neurologic injury is rare with pure flexion–distraction because retro-pulsion of bone fragments into the spinal canal seldom occurs. Asymmetric loss of the patellar reflex may be the only presenting sign. When canal compromise is present, patients may present with paraplegia or cauda equina syndrome. Compression of neural elements is most often via retropulsed bone fragments or misalignment from kyphotic deformity. Although it occurs rarely, the application of significant traction to the spinal cord during flexion–distraction can result in cord avulsion rostral to the level of injury. Intra-abdominal or retroperitoneal injury should be suspected in any child with a flexion–distraction injury, particularly one with lower abdominal ecchymoses (“seat belt” sign). The abdominal injury often overshadows the spine injury, or vice versa, in terms of severity and the need for acute treatment. It should always be assumed that the other injury type is present until it is adequately excluded with appropriate methods.

Radiographic Diagnosis

A lateral plain radiograph is the best initial study to screen for flexion–distraction injuries. Despite this, Chance fractures can be difficult to fully appreciate on lateral plain films. CT of the thoracolumbar spine should be performed if a fracture is strongly suspected but cannot be identified on plain radiographs. The classic finding on axial CT is the “empty facet” sign wherein the inferior articular surface of the rostral vertebra is no longer in close contact with the superior articular surface of the caudal vertebra at the level of the injury. It is important not to rely on abdominal CT to rule out a Chance fracture because imaging is often obtained only in the axial plane and a horizontal fracture may be missed, even on reconstructed sagittal images.⁹¹ Separation of the facet joints and widening of the interspinous space are most commonly seen in younger children because of the increased elasticity of their ligaments. It is very rare for instability to be demonstrated on flexion–extension imaging in a child with a flexion–distraction injury and a normal static radiograph. MRI is useful to determine the amount of associated ligamentous injury and to evaluate the neural elements in rare cases of neurologic deficit. If closed or open reduction is planned, MR imaging should be performed after acute abdominal injuries are addressed to assess whether occult compressive lesions are present.

Treatment

Patients with suspected intra-abdominal or retroperitoneal injuries should undergo prompt evaluation and treatment because these injuries may be life-threatening. Flexion–distraction injuries that are not associated with neurologic deficit or significant ligamentous injury can be treated conservatively with immobilization in a thoracolumbar orthosis. Children with fluctuating or progressive neurologic deficits should undergo operative decompression, reduction, internal stabilization, and fusion. Surgical stabilization and fusion should also be considered for children who have significant associated ligamentous injuries because these are less likely to heal with conservative management alone. Glassman et al concluded from a small series of seven children that those with a kyphotic deformity of less than 20 degrees could be treated with external bracing only, whereas those with more than 20 degrees of angulation required internal stabilization and fusion because their ligamentous injuries would not be able to heal adequately, resulting in inevitable curve progression.⁹² The time elapsed since the injury is another important consideration in a decision between conservative and operative management because injuries that have gone undiagnosed for a week or longer are less likely to be reducible and heal with external immobilization. Therefore, conservative management with external immobilization in a hyperextension orthosis for 12 weeks is most appropriate in children with flexion–distraction injuries who are neurologically intact, present immediately after the injury with less than 20 degrees of kyphotic angulation, with or without bony injury, and have no neural compression. Indications for surgical decompression, reduction, and internal stabilization include more than 20 degrees of kyphotic angulation at the level of injury, late presentation, inability to achieve a closed reduction, neural compression, and fluctuating or progressive neurologic deficits (which are indicative of ongoing instability).

Fracture–Dislocation

Injury Description

Fracture–dislocation injuries are caused by compressive, tension, rotation, or shear forces that result in damage to all three columns of the thoracolumbar spine. These injuries are highly unstable, with subluxation or dislocation of the rostral vertebral levels from the caudal ones. The incidence of neurologic deficits from concomitant SCI, including complete paraplegia, is very high. Fracture–dislocation injuries may be categorized into three subtypes: flexion–rotation, shear, and flexion–distraction. The flexion–rotation subtype typically results in complete disruption of the anterior and middle columns, with anterior wedging of the vertebral body and perched or jumped facets. Of note, child abuse has been known to result in this subtype of injury.⁸³ The shear subtype occurs when the force is directed in a posterior-to-anterior direction, resulting in the disruption of all three columns, including the anterior longitudinal ligament, with anterior displacement of the rostral vertebral levels. Fracturing of both the posterior arch of the rostral vertebral level and the superior articulating facet of the caudal level is typically observed.

The flexion–distraction subtype is similar to a Chance fracture associated with lap seat belt use, except for the addition of significant anterior wedge compression (approximately 10 to 20% loss of body height) or subluxation.

Clinical Presentation

Because of the large forces and degree of spinal column translation that are often involved, the majority of patients with fracture–dislocation injuries present with neurologic deficits due to nerve root or spinal cord compression. Of those presenting with deficits, approximately half have complete paraplegia.

Radiographic Diagnosis

The hallmark of a fracture–dislocation injury is subluxation or dislocation of the vertebral column rostral to the level of injury from levels caudal to the injury. This may be demonstrated on lateral plain radiographs of the thoracolumbar spine; however, in some instances, the injury may be reduced by the time imaging is obtained. Findings that suggest a fracture–dislocation injury are an increased interspinous distance, anterior wedging of the vertebral bodies (flexion–rotation and flexion–distraction subtypes), perched or jumped facets, facet fractures, horizontal laminar fractures, and a “free-floating” lamina from complete fracture of the posterior arch of the rostral level (shear subtype). Additionally, spinous process, apophyseal, multiple rib, hip, and pelvic fractures are associated with fracture–dislocation injuries. CT through the area of interest is particularly useful in defining the injury as well as planning for operative intervention. In flexion–rotation subtypes, there is often an intact posterior vertebral body wall with rotation and offset of adjacent vertebral bodies at the level of injury, resulting in spinal canal compromise. MRI should also be obtained through the area of interest, particularly in children presenting with neurologic deficits. It is useful for assessing the degree of neural compression, evaluating for intervertebral disk disruption and herniation, and determining the amount of associated ligamentous injury.

Treatment

The definitive treatment for fracture–dislocation injuries is operative decompression and reduction of the fracture, followed by internal stabilization and fusion. The ultimate goals of surgical intervention are to prevent additional injury to the neural elements and the development of subsequent deformity. Additionally, in children with concomitant SCIs, internal stabilization allows earlier and safer participation in rehabilitation programs. This is particularly important in the pediatric population because the incidence of significant neurologic recovery following severe SCI is higher in children than in adults.⁹³ A better prognosis is associated with younger age and an incomplete neurologic injury.

Apophyseal Ring Fracture

Injury Description

Apophyseal ring fractures are uniquely pediatric injuries in which a flexion mechanism results in fracture of the posterior

rim of the immature vertebral body end plate (the ring apophysis).⁸³ They most typically involve the adolescent lumbar spine. Retropulsion of the osseous fragment into the spinal canal, which can mimic a herniated intervertebral disk, may occur.

Clinical Presentation

The clinical presentation is similar to that of a herniated intervertebral disk. Symptoms typically include back pain with or without radicular findings, including radicular pain or weakness.

Radiographic Diagnosis

Apophyseal ring fractures may be difficult to appreciate on plain radiographs. CT or MR imaging may be needed to obtain a diagnosis. Given that a large number of patients present with symptoms similar to those seen with a herniated intervertebral disk, MRI is probably the best initial adjunct to plain radiographs. Additional unnecessary radiation exposure is also avoided in this case. Imaging will typically demonstrate fracture of the posterior aspect of the vertebral body end plate.⁹⁴ Retropulsion of an osseous fragment into the spinal canal may be seen on CT or MR imaging.

Treatment

Conservative management, including pain control, anti-inflammatory medications, physical therapy, and bracing, is typically the initial treatment for apophyseal injuries. Patients with large, centrally retropulsed bone fragments are at a higher risk for the development of chronic back pain.⁹⁵ Operative intervention is generally reserved for patients with retropulsed bone fragments and neurologic symptoms, or for those with pain refractory to conservative management.⁸³ Surgical management includes decompression with internal stabilization and fusion. Although historically anterior surgical approaches have been used to treat apophyseal avulsion fractures that occur at levels above the conus medullaris, posterolateral approaches for anterior decompression, posterior instrumentation, and anterior–posterior fusion have become more popular in recent years.

Spondylolysis and Spondylolisthesis

Injury Description

Spondylolysis is a defect of the pars interarticularis that may develop from repeated microtrauma (► Fig. 61.18, ► Fig. 61.19). It is found most commonly in adolescents who engage in physical activity, such as gymnastics and football, that involve repeated hyperextension.³⁰ The most commonly affected level is L5–S1, followed by L4–5. Spondylolysis can result in anterior spondylolisthesis of the cephalic, relative to the caudal, vertebral body. The Meyerding classification is the most widely accepted classification system for spondylolisthesis, with grades 1 and 2 being low-grade slips (<50% displacement) and grades 3 through 5 (>50% displacement) being high-grade slips.⁹⁶ Factors that are associated with the progression of spondylolisthesis are a diagnosis before the adolescent growth spurt, high-grade spondylolisthesis, and female gender.³⁰

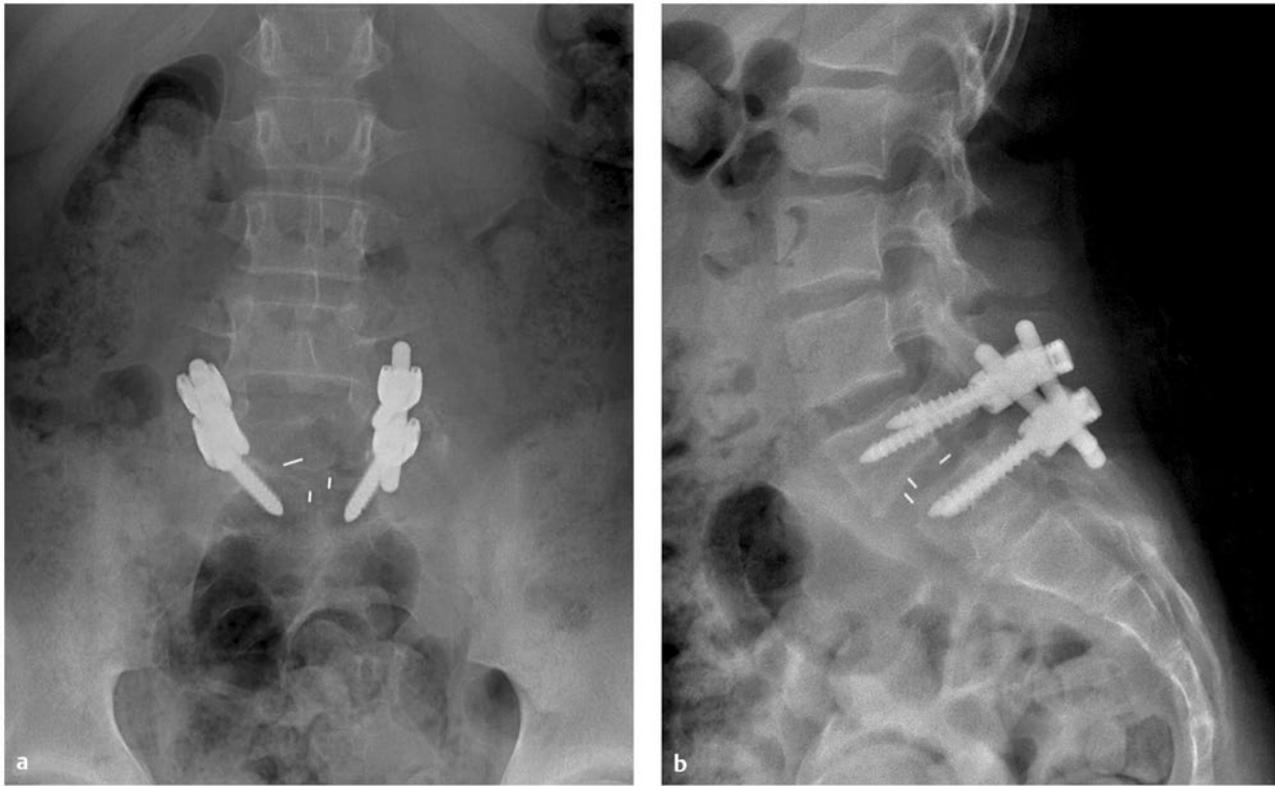

Fig. 61.19 Spondylolysis with spondylolisthesis. Postoperative (a) anteroposterior and (b) lateral radiographs demonstrating L5–S1 transforaminal interbody fusion and L5–S1 posterior segmental instrumentation performed in the same patient as in ▶ Fig. 61.18.

Clinical Presentation

Patients most commonly present with back pain exacerbated by activity. Radicular symptoms and neurologic deficit may also be present, particularly with higher-grade slips. A step-off may be detected on palpation of the spine in high-grade spondylolisthesis. Hamstring tightness is another frequent physical examination finding.³⁰

Radiographic Diagnosis

Spondylolysis and spondylolisthesis may both be demonstrated on lateral plain radiographs of the lumbar spine (▶ Fig. 61.18a). Grading of the degree of spondylolisthesis is also readily obtained from plain films. CT should be considered if spondylolysis is suspected but a pars defect is not clearly identified on X-ray and when operative intervention is planned (▶ Fig. 61.18b). MR imaging should be obtained when there is a neurologic deficit to appropriately evaluate the neural elements. It should also be considered in instances of high-grade spondylolisthesis to evaluate for associated intervertebral disk compromise or herniation because these may influence subsequent management.

Treatment

Acute spondylolysis with or without low-grade spondylolisthesis can be managed conservatively with activity modification,

pain medications, and bracing. Operative intervention for spondylolysis is rarely needed but is indicated if symptoms are refractory to conservative treatment; it is also indicated for progressive slips and spondylolysis with high-grade spondylolisthesis.³⁰ For isolated spondylolysis without spondylolisthesis, surgical intervention is typically geared toward a direct pars repair. If low-grade spondylolisthesis is present, in situ instrumentation with posterolateral fusion is the most common approach. Alternatively, high-grade spondylolisthesis is generally treated via partial reduction and decompression with instrumented fusion. This is most commonly accomplished through a posterior approach, such as a posterior or transforaminal lumbar interbody fusion (PLIF, TLIF), although an anterior approach with anterior grafting (i.e., anterior lumbar interbody fusion, ALIF) may be considered (▶ Fig. 61.19a,b).

SCIWORA

Injury Description

A detailed discussion of the medical management and outcomes of spinal cord injury without radiographic abnormality (SCIWORA) is beyond the scope of this chapter. However, the pathophysiologic basis for its occurrence are the specific anatomical and biomechanical properties of the pediatric spinal column discussed in Chapter 60. First described by Pang and

Wilberger in 1982, before the routine use of MRI, the term SCIWORA has historically been applied to traumatic myelopathy without fracture or subluxation identifiable on plain films or CT.⁹⁷ Two decades later, Pang published a review of SCIWORA summarizing the wealth of new information reported on the topic after its initial description.⁹⁸ SCIWORA is a uniquely pediatric injury resulting from the inherently increased flexibility of the developing spinal column. It primarily affects younger children and is associated with a high incidence of neurologic injury. SCIWORA results because the developing spinal column is more elastic than the mature spine and therefore able to accommodate significant intersegmental displacement at the moment of injury without fracture or ligamentous rupture. Horizontally oriented facets,^{71,99,100} wedge-shaped vertebral bodies,^{72,99} and an absence of uncinatous processes in the cervical spine³⁶ additionally contribute to the susceptibility of the pediatric spinal column to intersegmental movement. Hyperextension, flexion, distraction, and ischemic mechanisms have been implicated in SCIWORA. The displacement is momentarily large enough to cause significant SCI and is followed by spontaneous reduction of the dislocated segments. The result is a normal radiographic appearance of the spinal column on plain radiographs and CT.¹⁰¹

Age is associated with SCIWORA in three important ways. First, in children with traumatic myelopathy, the incidence of SCIWORA is higher in younger (0 to 9 years) children. Conversely, severe SCI in older children is more commonly associated with frank vertebral column disruption.³¹ Second, younger children with SCIWORA generally have more severe SCI than older children do.¹⁰² Third, SCIWORA most commonly affects the upper cervical spine in young children, whereas in older children the incidence of injury to the lower cervical levels is increased. This is explained by the high degree of inherent flexibility in the cervical versus the thoracic spine and the fact that the fulcrum for maximal flexion-extension is at a progressively lower level within the subaxial cervical spine as the spinal column matures (C2-3 in infants, C3-4 by the age of 5 to 6 years, and C5-6 in adolescents and adults). Conversely, SCIWORA involving the thoracic cord is distributed evenly in all pediatric age groups because the thoracic spinal column matures more gradually than the upper cervical spine.¹⁰² SCIWORA involves the thoracic cord in approximately 15% of cases and generally occurs after violent trauma with severe distraction (i.e., high-speed motor vehicle accidents or lap seat belt use) or posterior-to-anterior crush injuries (i.e., children crushed by a slow-moving vehicle and presenting with tire tracks on the back).¹⁰²⁻¹⁰⁹

In addition to the initial SCI, SCIWORA results in occult instability of the spinal column. Although the stabilizing ligaments and soft tissues of the spine are elastic enough to undergo transient stretching and recoil without rupture, MRI findings indicate that they are often partially torn or severely sprained.^{36,110} In this situation, the spinal column is vulnerable to excessive motion with repeated, even innocuous, stress. This places the spinal cord at further risk, and it may be reinjured if the occult instability is not properly treated, resulting in delayed neurologic deterioration and recurrent SCIWORA.

Clinical Presentation

Children with SCIWORA generally present with traumatic myelopathy, most frequently localized to the cervical spine. Some children with SCIWORA (22 to 67%) do not have immediately detectable neurologic deficits; rather, the deficits develop in a delayed fashion after a period of minutes to days.^{81,97,106,110-113} This phenomenon may be explained by undiagnosed occult instability of the spinal column resulting from the initial trauma, predisposing the affected child to repeated spinal cord insults and subsequent neurologic injury from only minor forces. This concept is supported by observations that SCIWORA may recur up to 10 weeks after the initial trauma.¹¹⁴ Importantly, neurologic deficits from recurrent SCIWORA are generally more severe than those from the initial injury.¹¹⁴ Children with thoracic SCIWORA have a high incidence of associated thoracic, abdominal, and pelvic injuries.

Radiographic Diagnosis

The radiographic evaluation of a child with a neurologic deficit begins with a complete spine survey. If plain films are normal, fine-cut CT through the level of the deficit is obtained to assess for occult fractures. SCIWORA, by definition, does not result in abnormalities of the spinal column, such as fractures or evidence of gross instability (i.e., subluxation), on static or dynamic plain films or on CT. Rather, SCIWORA results in occult instability, in contrast to the overt instability seen in spinal column injuries like fracture-subluxation and subluxation without fracture (purely ligamentous injuries).^{36,71,99,100,110,115} Associated muscle spasm following spine trauma has been demonstrated to obscure even gross instability; therefore, the concept of occult instability is not contradicted by the failure of dynamic imaging to demonstrate pathologic movement.¹¹⁶

Prompt MR imaging is crucial in the evaluation of children with neurologic deficits localizing to the spinal cord. In children with SCIWORA, MRI frequently demonstrates abnormalities of the neural and extraneural soft tissues of the spine.¹¹⁷ Extraneural findings correlate with the mechanism of injury and correspond to the level of the neurologic deficit.³⁶ Typical findings include partial tearing or rupture of the anterior longitudinal ligament (hyperextension) or posterior longitudinal ligament (hyperflexion), intravertebral disk hemorrhage (translational/shearing forces), tectorial membrane tearing and hemorrhage, and interspinous and interlaminar ligament hemorrhage (distraction). Because extravasated blood is converted within hours to methemoglobin in nonneural tissues, extraneural injuries associated with SCIWORA are discernable on T1-weighted MR imaging sequences very soon following injury.³⁶ The majority of patients with SCIWORA will also have neural tissue injury demonstrable on MRI, including complete disruption of the spinal cord, major cord hemorrhage (>50% of the cross-sectional area of cord), minor cord hemorrhage (<50% of the cross-sectional area), or spinal cord edema only.³⁶ Although approximately one-quarter of patients with SCIWORA will fail to demonstrate any spinal cord abnormality on MR imaging, the vast majority

of them will have demonstrable ligamentous injury. Therefore, in the modern era, SCIWORA should be used to describe patients with neurologic injury who have no radiographic abnormalities on any imaging study, including plain and dynamic radiographs, CT scans, and MR images.

Treatment

Like that of any case of suspected spine or spinal column trauma, the management of a child with SCIWORA begins in the field with prompt immobilization and resuscitation. As discussed in Chapter 60, care must be taken in infants and young children to prop up the thorax from the shoulders down to maintain a neutral alignment and avoid inadvertent flexion of the neck. SCIWORA should be considered a diagnosis of exclusion. In a child with a neurologic deficit, it is imperative to rule out head trauma, compressive lesions of the spinal cord (i.e., epidural hematoma, intervertebral disk herniation), and injuries resulting in gross instability (i.e., fractures, purely ligamentous injury) as causes of the deficit because these may require more specific and prompt surgical intervention. This is achieved through a combination of static and dynamic plain radiographs, fine-cut CT, and MR imaging, as previously discussed. Patients with cervical or thoracic SCIWORA should be initially maintained with a hard collar or with strict bed rest and log rolling only, respectively. Based on the results of the National Acute Spinal Cord Injury Study II (NASCIS II), children with nonpenetrating SCIs, including SCIWORA, whose injury is diagnosed within 8 hours of onset are generally begun on a 24-hour course of high-dose corticosteroids.¹¹⁸

SCIWORA results in occult instability of the spinal column wherein the spinal cord is vulnerable to repeated injury during seemingly normal activity or minor trauma. This may result in delayed neurologic deficits that are more profound than those of the initial SCI. The primary treatment for children with SCIWORA is external immobilization with a rigid cervical brace (for cervical SCIWORA) or a thoracolumbar orthosis (for thoracic SCIWORA) and activity restrictions for several months. Some authors have reported repeated injury after only 2 months of immobilization, but no recurrent injuries when the duration of immobilization was at least 3 months.³⁶ Repeated flexion–extension radiographs should be obtained in a delayed fashion to assess for late instability.

61.2 Conclusion

There exists a wide array of possible injury types following trauma to the pediatric spinal column. A thorough understanding of the underlying anatomical, biomechanical, and neurologic consequences of these injuries, along with their associated clinical and radiographic findings, is necessary for their prompt and appropriate management through both nonoperative and surgical techniques.

Pearls

- AOD should be suspected in any child involved in an appropriate high-velocity mechanism (i.e., a pedestrian–motor vehicle accident), especially one presenting with facial injuries or initial cardiopulmonary instability.
- AOD may result in subtle radiographic findings. Because early diagnosis is paramount to mitigate additional, potentially catastrophic neurologic injury, when AOD is suspected there should be a relentless pursuit of findings to either confirm or exclude the diagnosis.
- True odontoid fractures are rare in children. Rather, they are frequently epiphysiolysis at the dentocentral synchondrosis, located just below the base of the dens in the rostral C2 body, which is not fused until 8 to 11 years of age.
- Traumatic injuries to the subaxial cervical spine are most efficiently classified into purely ligamentous injuries, osseous anterior column injuries, osseous posterior column injuries, and combined anterior and posterior column injuries.
- Thoracic and lumbar spinal column injuries are much less frequent than cervical injuries in the pediatric population. Similar injury types are seen in both the thoracic and lumbar spine; of these, fracture–dislocations are most commonly associated with neurologic deficits.
- Apophyseal ring fractures may mimic a herniated intervertebral disk; however, typically they are less likely to respond to conservative management and more frequently require surgical intervention.
- SCIWORA results in occult instability of the spinal column, with a significant risk for repeated injury to the spinal cord and profound delayed neurologic deficits after even minor or innocuous trauma. Prompt treatment with external immobilization is warranted.

62 Spinal Cord Injury

Joseph H. Miller and Curtis J. Rozzelle

Trauma is the leading cause of death and disability in the pediatric population. Spinal cord injuries, despite involving only 1 to 2% of all pediatric trauma cases, can be incredibly debilitating, requiring a lifetime of care and utilization of medical resources.¹⁻⁷ Spinal cord injury (SCI) affects approximately 2 per 100,000 children per year, and the National Spinal Cord Injury Statistical Center (NSCISC) found in 2010 that 9.86% of patients with SCI were younger than 18 years.^{8,9} The vast majority of injuries involve the cervical spinal cord, whereas only 5.4 to 34% involve the thoracolumbar spine.^{1,8,10,11}

The pediatric spine is not merely a miniature version of the adult spine. Instead, the developing spinal column is inherently more elastic and mobile. The hypermobility of the pediatric spine provides less protection to the fragile, underlying spinal cord.¹² A newborn spine and a 14-year-old spine lie along a biomechanical continuum that becomes less mobile and more rigid as a child transitions into late adolescence and adulthood. The differences between adults and children are not limited to biomechanics; rather, there are clinically important differences in regard to injury pattern, treatment, rehabilitation, and outcomes.

62.1 Epidemiology

The epidemiology of pediatric SCI is difficult to characterize fully because of the limited available data on this patient population.¹³⁻¹⁵ The extant literature contains few studies that include pediatric patients, typically excluding those treated at adult institutions, who die before arrival at a hospital, or who have birth-related SCI. Potential evidence as to the degree of underreporting in children can be extrapolated from adult data. Most authorities illustrate the increased susceptibility of the pediatric spine to injury. Milby et al, in a pooled analysis of 281,864 adult patients with trauma, found a prevalence of SCI of 3.7% in the adult population.¹⁶ One would expect that pediatric patients with trauma would have an incidence of SCI above 1%.

The incidence of SCI is approximately 1.99 to 7.4 per 100,000, and approximately 1,455 children are admitted each year in the United States with SCI.^{8,17-19} The prevalence within the pediatric population is poorly characterized but can be estimated based on age at injury. The prevalence of SCI in both adults and children is between 223 and 1,009 per million inhabitants, with fewer than 10% of injuries occurring before the age of 18 years.^{13,14} Lasfargues et al demonstrated the prevalence of SCI in the United States in 1988 to be 176,697, with 11,745 (6.6%) of patients younger than 24 years.²⁰ The NSCISC found in 2010 that 9.86% of patients with SCI were younger than 18 years.⁹ The same data demonstrated that only 1% of spinal cord injuries occurred in patients younger than 13 years. There is an obvious age distribution, with a mean age of 10.3 to 13.5 years and a median age closer to 16 years.^{6,21} Younger patients have a lower rate of SCI, and the incidence rapidly increases with age. Although motor vehicle accidents remain the leading cause of SCI across all age groups, the age of the victim is also pertinent

to the mechanism of injury. Older persons tend to engage in higher-risk activities, whereas younger people are more susceptible to nonaccidental trauma. The gender distribution tends to be more even in younger patients, with the male-to-female ratio of persons with injuries increasing toward adolescence and adulthood.⁴

Pediatric SCI is more common in males, with reported male-to-female ratios as high as 3:1.^{4,8,21-24} The gender distribution is a result of increased risk-taking behavior as children age. Sports-related injuries are rarely seen before the age of 9 years. After 9 years of age, sports-related injuries contribute to approximately 25% of pediatric cases of SCI in the United States, and most of these occur in males.²¹ Brown et al demonstrated that the numbers of males and females involved in motor vehicle collisions were almost equal, with a male-to-female ratio of 1.2:1, but for sports-related injuries, the ratio was 3.5:1.²¹

Race also appears to play a role in the epidemiology of pediatric SCI. In the United States, Caucasians have the highest rate and account for the majority of cases of SCI. African Americans exhibit the second highest rate of SCI (1.53 per 100,000), followed by Native Americans (1.00 per 100,000), Hispanics (0.87 per 100,000), and Asians (0.36 per 100,000).^{8,19}

Pediatric SCI is a rare disease entity and as such is not a major international public health concern. Consequently, few geographic data exist outside the developed world. Several interesting cultural trends are apparent from the available literature. Cripps et al performed a global epidemiologic review of SCI and made several observations. In Turkey, a high percentage of SCIs occur after falls from rooftops because children often sleep on the roof in summer.¹³ Southern Asia, specifically Nepal and Pakistan, have a similarly high incidence of falls from rooftops and trees that result in SCI.^{13,25} In Greece and Italy, young males are known for engaging in high-risk driving behaviors that place them at increased risk for SCI.^{7,26} Epidemiologic studies in the pediatric population would be most helpful in terms of directing future research into prevention and management of patients with SCI.

62.2 Biomechanics and Anatomy

The biomechanics of the developing spine and spinal cord have been the subject of much discussion but little research because of the difficulty in conducting the studies in children. Nonetheless, the developmental anatomy and subsequent biomechanical differences in the pediatric spine are felt to play a central role in the understanding of pediatric spine trauma.

Embryology is always a fitting starting point for understanding any anatomical process. The developing fetal spine derives from paraxial mesoderm that is located lateral to the neural tube. The paraxial mesoderm develops into paired somites that then form the axial skeleton and its associated ligaments, tendons, and muscles.^{27,28} The demarcation of individual vertebrae takes place through a process known as resegmentation, in which the anterior and posterior portions of adjacent somites fuse.^{27,29,30} Each vertebral body is thus formed from

two sclerotomes, unlike the peripheral nervous system. The intervertebral disks are formed at the boundary between the anterior and posterior sclerotomal portions of the somite.²⁸ The development of the spine begins in utero and continues until early adulthood.

Ossification of the atlas and axis is unique compared with that in the remainder of the subaxial spine. The anterior arch of C1 is typically ossified by the age of 1 year, and complete ossification of the posterior arch occurs around the age of 3 years.³¹ The atlas achieves a normal adult radiographic appearance by the age of 7 years.³² The axis is more complex in that there are a total of six ossification centers (unlike the typical four at other spinal levels); these are involved in the formation of the odontoid process. The odontoid process begins to fuse to the body of C2 between the ages of 3 and 6 years.³² This process is normally completed by the age of 11 years.³² Ossiculum terminale is a condition in which the secondary ossification center at the apical portion of the odontoid does not fuse by the age of 12 years.³³ Ossiculum terminale is commonly seen on adult radiographs and usually carries no clinical significance, although several case reports suggest there may be an association with atlantoaxial instability.³⁴ Mortazavi et al noted that the C2 posterior arch fuses in the midline by the age of 3 years and with body between the ages of 3 and 6 years.³³

Os odontoideum, a nonunion of the synchondrosis of the odontoid process that is associated with pathologic instability, is clinically distinct from ossiculum terminale. Radiographically, the two can be differentiated by the location of nonunion. Os odontoideum is considered by most authorities to be inherently unstable regardless of findings on dynamic plain films. Klimo et al described three patients with known os odontoideum who were followed nonoperatively and experienced SCI.³⁵ Surgical management is thus recommended to minimize risk for subsequent SCI (see box “Predisposing Conditions for Spinal Cord Injury (p.834)”).

Predisposing Conditions for Spinal Cord Injury

- Congenital cervical stenosis
- Down syndrome
- Morquio syndrome
- Chiari type 1 malformation
- Os odontoideum

The subaxial cervical spine from C3 to C7 typically follows a very similar ossification pattern. The ossification of the posterior arch follows the same pattern as C2, and the posterior arch is typically fused with the body by age 6. Complete ossification typically does not occur until age 25.³² Central to an understanding of spinal radiographs in children is the ability to recognize epiphyseal variants, incomplete ossification of synchondroses and apophyses, unique vertebral architecture, pseudosubluxation of C2 on C3, overriding of the anterior atlas in relation to the odontoid in extension, and varied atlantodental intervals.^{36–40} The pediatric spine is thus unique in terms of stability, injury patterns, clinical and radiographic evaluation, and treatment (► Fig. 62.1a–c).

The stability of the spine is a function of the connecting ligaments, facets and articular capsules, intervertebral disks, and associated musculature. The increased proportional weight of a child's head with respect the remainder of the body increases the mechanical strain on the cervical spine during extremes of flexion, extension, rotation, and distraction.^{12,41,42} The neck acts as a fulcrum, and the larger head effectively lengthens the moment arm, thus increasing the force placed upon the underdeveloped cervical spine. In addition to the increased forces acting on the spine, the pediatric cervical diskoligamentous complex has been shown to be considerably more elastic than that in adults.^{32,38,42–45} The ramifications of increased elasticity are that the spine can bend but not break during trauma. Unfortunately, the spinal cord does not well tolerate stretching and is thus felt to be more susceptible in the pediatric population. The ligaments, joint capsules, and intervertebral disks have different characteristics, as does the bony anatomy of the articulations themselves.

The occipitoatlantoaxial joints are an incredibly complex bony and ligamentous region of the most cephalic portion of the spinal column and are involved in many pediatric SCIs. The occipital condyles, although infrequently fractured, have associated ligamentous structures involved in atlanto-occipital dislocation.^{46,47} Additionally, the shape of the occipital condyle and the shallow articulation with the lateral mass of C1 put the vertebral artery at risk for injury during hyperextension.⁴⁸

Pang and Zovickian have written several overviews of the morphometric differences between the adult and pediatric cervical spine that have implications with regard to spinal cord injuries.^{12,42} They explain that the facet joints are “... shallow and oriented more horizontally than in adults,” and this is felt to increase the potential for unintended translation.^{12,42} The potential for forward translation is also increased in children by the anterior wedging of vertebral bodies.^{32,42–44} The uncovertebral joints (joints of Luschka) are stabilizing joints of the subaxial spine that chiefly limit lateral movement.⁴⁹ Orofino et al studied the uncovertebral joints of 11-week-old fetuses to full-term infants and found no synovial tissue at the future site of the uncinat process, confirming observations in adults that the uncovertebral joints are not true synovial joints.⁵⁰ Despite not being true synovial joints, unlike the facets, they do provide a mechanical advantage in preventing lateral movement and a degree of rotation.^{33,51} The uncinat processes and uncovertebral joints are not formed until around the age of 10 years and continue to develop into adulthood.^{49,52} The incompletely developed subaxial spine contributes to instability and increases the risk for SCI in children.

The diameter of the spinal canal is another important consideration. According to Steel's “rule of thirds,” which was proposed in 1968, the spinal canal at C1 is filled with (1) odontoid process, (2) spinal cord, and (3) cerebrospinal fluid “dead space” in equal proportions.^{53–55} Jauregui et al found that Steel's rule of thirds is maintained throughout childhood, with the average diameter available for the spinal cord in neonates being approximately 12.4 mm.⁵³ The median diameter of the canal at C2 was found by Wang et al to increase from between 12.27 and 12.79 mm at 6 months to between 15.75 and 16.00 mm at 13 years.³¹ After 13 years of age, the diameter of the spinal canal stabilizes to the adult range. When the smaller canal diameter is coupled with forces that result in hyperextension, the spinal

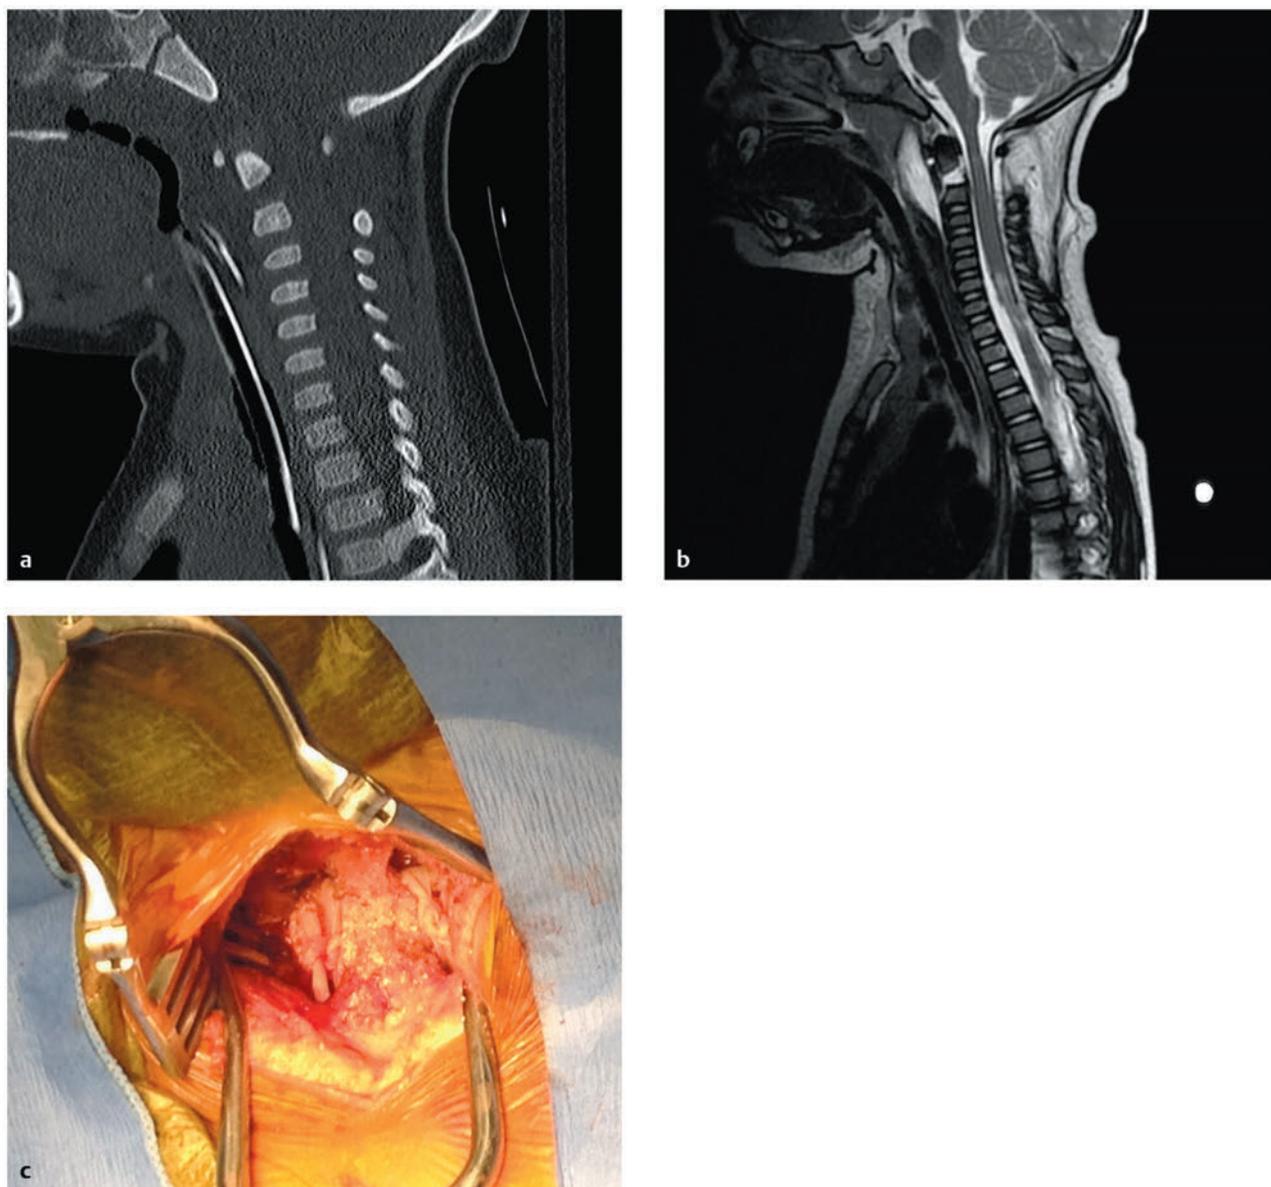

Fig. 62.1 An 18-month-old girl in a forward-facing car seat during a motor vehicle collision. (a,b) The patient presented with an American Spinal Injury Association (ASIA) class A spondylolisthesis fracture of C2 that was placed in a halo. (c) The patient subsequently underwent internal fixation with Mersilene (Ethicon, Somerville, NJ) tape between C1 and C2.

canal diameter can be further decreased by up to 50% simply from the inward buckling of the ligamentum flavum.^{12,56–58}

62.3 Thoracolumbar Injuries

Thoracolumbar fractures most often occur in older children and infrequently lead to SCI (14.6%).¹¹ Dogan et al reviewed 89 patients with thoracolumbar injuries and found motor vehicle accidents to be the most common mechanism.¹¹ The classification

of thoracolumbar fractures in the pediatric population is not characterized, but the thoracolumbar injury classification and severity score (TLICS) may be used.^{59,60} For instance, purely ligamentous injuries (1.1%) without any bony involvement are classified as distracting injuries with interruption of the posterior ligamentous complex. The utility of the TLICS system in children is the consideration of ligamentous involvement and the neurologic examination (see box “Thoracolumbar Injury Classification and Severity Score” and ► Fig. 62.2a,b).

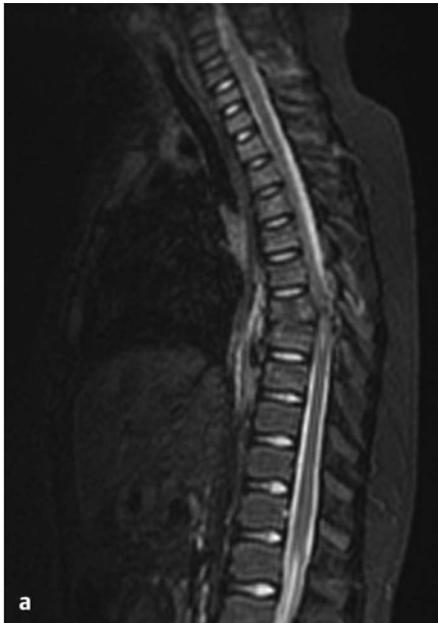

Fig. 62.2 An 11-year-old girl unrestrained in a motor vehicle collision presented with an American Spinal Injury Association (ASIA) class A injury at the T7 level. (a) Her thoracolumbar injury classification and severity score (TLICS) was as follows: morphology, 3; posterior ligamentous injury, 3; neurologic injury, 2. (b) The patient underwent decompression, internal fixation, and fusion. She now ambulates with a walker (ASIA class D) and has normal bowel and bladder function.

Thoracolumbar Injury Classification and Severity Score

Injury morphology

- Compression
- Burst
- Translational/rotational
- Distraction

Integrity of posterior ligamentous complex

- Intact
- Suspected/indeterminate
- Injured

Neurologic status

- Intact
- Nerve root
- Complete: American Spinal Injury Association (ASIA) class A
- Incomplete
- Cauda equina syndrome

62.4 Birth Injuries

Birth-related SCI is rare and is estimated to affect approximately 1 in 60,000 live births.^{61–63} Birth injuries are difficult to diagnose and are a highly litigated form of pediatric SCIs.^{63–65} The neurologic examination in a neonate is difficult. Normal reflexes can mask an underlying complete cord transection. Upper cervical SCI can present with respiratory insufficiency, hypotonia, and quadriplegia. Lower cervical SCI demonstrates abdominal breathing (due to paralyzed intercostal muscles) in addition to lower extremity hypotonia.⁶³ An important and underappreciated element in the examination of a neonate is the facial reaction to painful stimuli. Reflexive withdrawal of the extremities without grimacing or crying is the hallmark of neonatal SCI. Additionally, Horner syndrome or brachial

plexus injury provides evidence of a difficult delivery and potential SCI.

Not all cases of neonatal SCI occur during delivery; multiple reports in the literature document prenatal SCI.^{63,65–67} The management of birth-related SCI requires ascertaining a diagnosis and evaluating for potential operative intervention. Blount et al described a spontaneous cervical epidural hematoma that mimicked a birth-related SCI and later required surgical decompression.⁶⁵

62.5 SCIWORA

SCI without radiographic abnormality (SCIWORA) is a subtype of SCI that was initially described by Pang and Wilberger in 1982.⁶⁸ They described 24 patients with SCI on examination without imaging abnormalities on plain films, computed tomography (CT), or myelography. Magnetic resonance (MR) imaging, a nonradiographic form of imaging, is abnormal in approximately 15 to 65% of patients with SCIWORA.^{62,69} Thus, the presence of neural or extraneural abnormalities on MR imaging does not exclude the diagnosis, although the semantics of the term remain controversial. For instance, a patient with instability on flexion–extension radiographs does not have SCIWORA, but ligamentous hyperintensity on STIR (short tau inversion recovery) MR imaging suggesting instability would not preclude the diagnosis. Further standardization of the term will limit confusion in the literature and clinical setting. The incidence of SCIWORA in the pediatric population with SCI is 34.8% (range, 5 to 67%).⁷⁰ As mentioned previously, the spinal column elasticity of younger children leads to a higher rate of SCIWORA.⁷¹

The 2012 Guidelines for the Management of Acute Cervical Spine and Spinal Cord Injuries, citing level 3 evidence, recommend that the initial evaluation of a patient with SCIWORA include MR imaging, radiographs of the entire spinal column, and flexion–extension plain films.⁶⁹ Normal MR imaging portends a good outcome. Bosch et al and Pang independently reported complete recovery in all patients with SCIWORA who

had normal MR imaging ($n = 50$).^{70,72} There are small case studies of patients with normal MR imaging and deficits persisting beyond 1 year.⁷³ Pang further stratified findings into major hemorrhage, minor hemorrhage, and edema.⁷⁰ The degree of SCI seen on MR imaging was directly related to outcome.

MR imaging findings can vary depending on patient age and on the level, mechanism, and extent of injury. MR imaging in the acute setting may identify cord signal change, compressive lesions, and/or ligamentous injury. Epidural hematomas, disk herniations, and other compressive lesions resulting in SCIWORA require operative decompression. MR imaging also can demonstrate ligamentous injuries, especially on T2 and STIR sequences, that suggest instability.^{72,74,75} Mortavazi et al restated the previous recommendations of Pollack et al from 1988 to repeat MR imaging 6 to 9 days after the initial injury.^{33,76} The quality of MR imaging and the sequences performed have changed significantly since 1988. Nonetheless, in a patient with normal initial MR imaging and a persistent neurologic deficit, repeated imaging is warranted (► Fig. 62.3a–c). Flexion–

extension lateral radiographs are potential adjuncts to clearing the cervical spine and ruling out instability in SCIWORA. Paraspinal muscle spasms may prevent adequate flexion for several days after injury.⁷⁷ Pang also recommends somatosensory evoked potential (SSEP) testing in all patients with SCIWORA, although the clinical utility is not well characterized in the literature.

The surgical treatment of patients with SCIWORA depends on the presence of compressive pathology and/or instability. The vast majority of patients, however, will not have a surgical indication. Activity restriction thus becomes important to promote recovery and prevent recurrent injury. Pollack et al studied 8 patients (19%) with recurrent SCIWORA and found most surgical indications to occur within the first week (62.5%) and all to occur within 10 weeks.⁷⁶ As a result of this and similar studies, external immobilization is recommended for up to 12 weeks following injury, and patients are encouraged to avoid “high-risk” activities for 6 months.^{12,69,76}

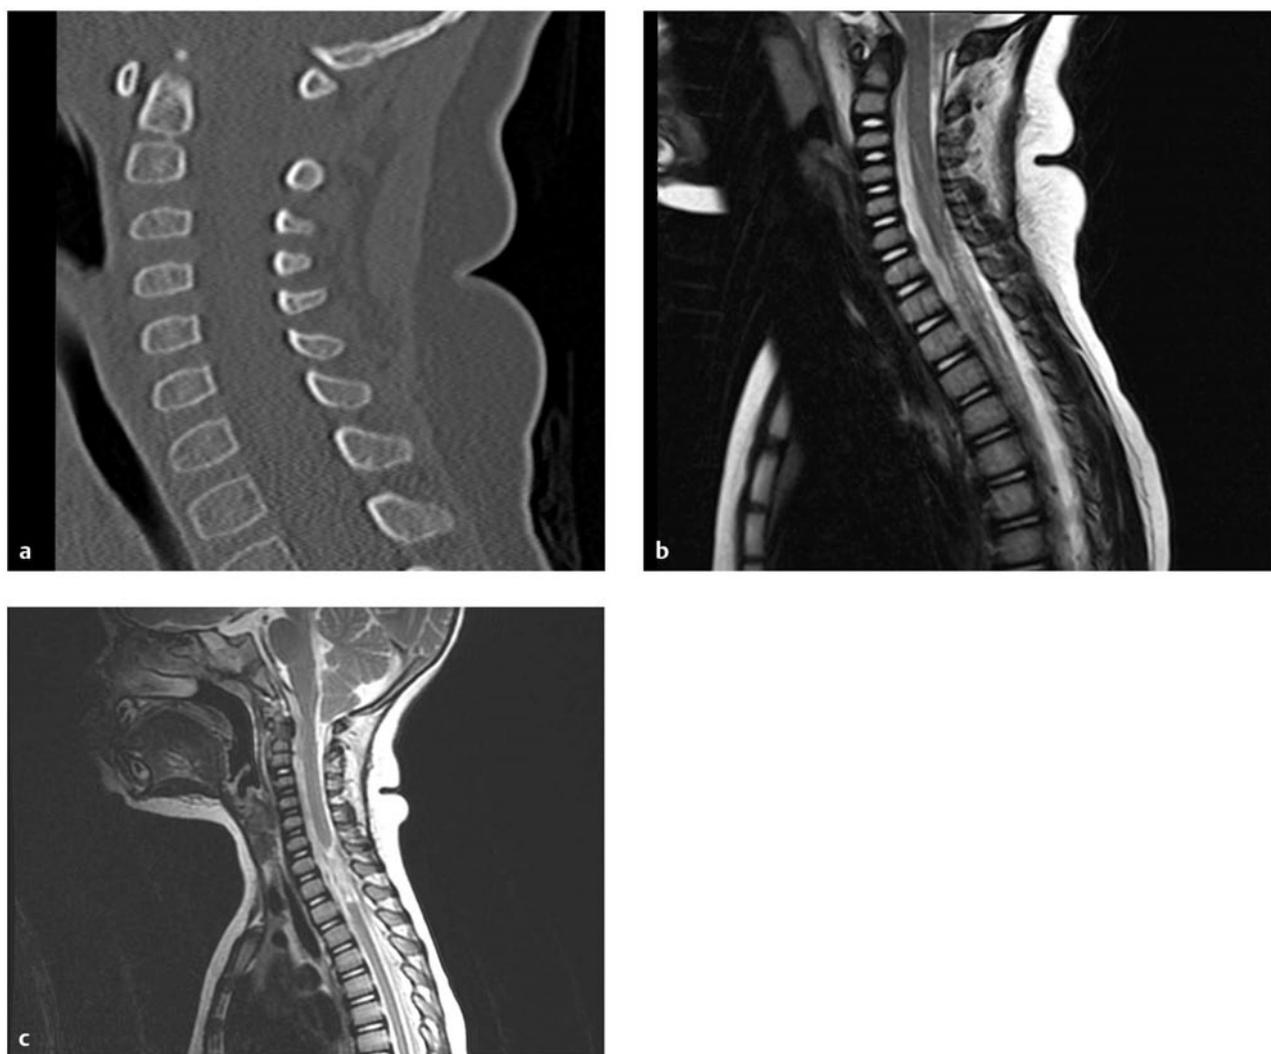

Fig. 62.3 A 2-year-old boy after a motor vehicle collision with a T2 level American Spinal Injury Association (ASIA) class A injury and no discernible spinal column injury. (a) Image obtained less than 24 hours after injury. (b) Image obtained 9 days later demonstrates retraction of the severed cord ends. (c) Two years after injury, late instability had not developed.

62.6 Initial Stabilization and Evaluation

The management of pediatric cervical spine injuries begins immediately at the scene of the accident. Education of the general public and emergency medical personnel is a vital adjunct to in-patient care. The first step in the initial evaluation of any trauma is management of the airway, breathing, and circulation. Maintaining adequate oxygenated perfusion to the injured spinal cord is a central tenet in management and should begin as quickly as possible.⁷⁸ During the primary survey, the cervical spine should be held in in-line immobilization and manipulated as little as possible. A cervical collar of appropriate size should be placed, or the head should be immobilized with rolls. A collar that is too large will not provide adequate immobilization and may place the cervical spine in excessive distraction. Because the head-to-body ratio is larger in children than in adults, patients less than 8 years old should be placed on a back board with either an occipital recess or thoracic bolsters to avoid untoward cervical flexion and maintain neutral alignment.^{79,80} The proper initial treatment of a child with an unstable cervical spine may prevent secondary SCI.

Following the initial evaluation and stabilization, a more in-depth assessment of the patient must be performed. The clinical history and physical examination are paramount to medical decision making regarding radiographic evaluation and the potential treatment of any injuries. There is no level 1 evidence in pediatric spine trauma, but level 2 and 3 evidence provides some guidance on imaging.

In the absence of a neurologic deficit, patients who are awake, alert, communicative, without midline cervical tenderness, not intoxicated, and without painful distracting injuries typically do not need cervical spine imaging.^{6,33,69,81} Patients who do not fulfill these criteria, children younger than 3 years who are involved in motor vehicle collisions or falls from more than 10 feet (especially those with axial loads to the head), and suspected victims of nonaccidental trauma should undergo radiographic evaluation of the cervical spine.^{6,82,83} Visualization of the cervicothoracic junction may necessitate the use of a swimmer's view if plain radiographs are obtained. In general, children younger than 3 are considered noncommunicative and according to Anderson et al require imaging following trauma.^{82,84} Viccellio et al performed the largest prospective randomized trial on the evaluation of pediatric cervical injuries. Use of the aforementioned criteria, outlined by the National Emergency X-Radiography Utilization Study (NEXUS), had a sensitivity and negative predictive value of 100% in ruling out pediatric cervical spine injuries.^{6,85,86} Flexion–extension plain films, CT, and MR imaging are all used adjunctively in the radiologic clearance of a pediatric cervical spine. Clearance of the cervical spine requires that both radiologic and clinical criteria be met.

Children with a neurologic deficit and suspected spinal cord injuries require CT and MR imaging evaluation. MR imaging is especially beneficial in obtunded patients with suspicious imaging and should include T2 and STIR sequences to evaluate for acute ligamentous injury and SCI.^{33,87,88} Additionally, radiographic evaluation of the remainder of the spine is recommended to avoid missed noncontiguous injuries that may not be clinically apparent because of the presence of a proximal SCI.

Firth et al found that 11.8% of children with a spinal injury had a noncontiguous fracture.⁸⁹

SSEPs and neurogenic evoked potentials are poorly studied in the pediatric trauma population. In patients with incomplete SCIs, they may have some diagnostic utility.^{69,70,90,91} Pang recommends the routine use of SSEP testing in patients with suspected SCI, especially in the setting of SCIWORA.⁷⁰ He states that SSEP testing (1) detects subtle abnormalities in the posterior column conduction pathway when the clinical examination is inconclusive, (2) helps detect SCI in head-injured children, (3) is the only feasible assessment in comatose patients or those requiring neuromuscular blockade, and (4) is occasionally useful in distinguishing between brachial plexus, intracranial, and spinal cord injuries.⁷⁰ Scarrow et al performed a pilot study in which flexion–extension plain films with concomitant SSEP testing were obtained during the clearance of cervical collars in obtunded patients.⁹² Only 1 of 15 patients studied had flexion–extension films and SSEPs that were both abnormal. This patient's MR imaging was normal, and his collar was later clinically cleared. Four additional patients had abnormal SSEPs, but the one patient with a SCI had normal SSEPs. Further study is warranted to determine the utility of SSEP testing in the pediatric population.

Concomitant vascular injury may be associated with traumatic cervical SCI. The occurrence of traumatic carotid or vertebral artery dissections in children is very low.⁹³ In the absence of penetrating injuries, CT or conventional angiography is not routinely indicated in the pediatric population.

62.7 Evidence-Based Treatment and Management

A definitive evidence-based approach to the management of pediatric SCIs does not exist. The injuries are rare, varied, and poorly studied in the literature. Nonetheless, these patients deserve high-quality care. The only way to reconcile our predicament is to use the available pediatric literature, make inferences based upon adult data, and draw from experience.

The pharmacologic treatment of spinal cord injuries, specifically the use of methylprednisolone, remains a controversial topic. The only randomized controlled trial to include children was the National Acute Spinal Cord Injury Study (NASCIS) II.⁹⁴ The results of this trial did not specifically address outcome in the group of 13- to 19-year-old patients who were 14.9 to 15.4% of each of the three treatment arms. The stratification for age and outcome was not statistically significantly different, and the results of the trial have been the subject of considerable controversy. The initial outcome measures of the study were not met, but the authors described an a priori hypothesis that greater clinical improvement could be obtained with earlier initiation of the methylprednisolone treatment protocol.⁹⁴ Bracken, the lead author of the three NASCIS trials, noted that the treatment effect of NASCIS II was relatively minor.⁹⁵ The expected motor improvement, based on Japanese, French, and American randomized controlled trials, is unilateral improvement in the motor score of 4.1 points.^{64,94–97} The score used in these trials consisted of Medical Research Council (MRC) motor grades 0 through 5 in 14 motor groups (total score, 140 per patient). According to the post hoc analysis, a patient could be expected to

have unilateral improvement of approximately one complete motor level.⁹⁵ The effect is thus not nearly as definitive as the conclusions in the original articles or in the January 2012 Cochrane Review written by the same author.^{64,94,95,98–100} The latest (2008) adult guidelines of the Consortium for Spinal Cord Medicine, an organization to which the American Association of Neurological Surgeons and Congress of Neurological Surgeons belong, do not recommend starting steroids and actually recommend stopping steroids, if they were started at another facility, as soon as possible to avoid adverse complications.¹⁰¹

Wang et al studied 30 cases of SCI in children and found methylprednisolone administration to be unrelated to neurologic improvement ($p=0.31$).¹⁰² It is important to note that only 8 children received steroids, and 5 (62.5%) had some neurologic improvement.¹⁰² The 2002 guidelines for the management of pediatric cervical spine and spinal cord injuries and the 2012 guidelines for the management of acute cervical spine and spinal cord injuries cite insufficient data to comment on steroid use in children.^{69,81} A well-powered and designed multicenter randomized controlled trial is necessary before methylprednisolone can be recommended for SCIs in the pediatric population.

Perfusion to the injured spinal cord is important during the management of acute injuries. The denervation of sympathetics, in addition to any systemic injuries sustained, may result in distributive hypovolemia, hypotension, and even neurogenic shock. Maintenance of an age-appropriate physiologic mean arterial blood pressures (MAP) is recommended in the treatment of any patient with trauma.¹⁰³ Augmentation of the blood pressure has been advocated in patients with SCI to prevent secondary injury from hypoperfusion.^{78,104–108} The two principal studies for MAP management in adults both used methylprednisolone according to the NASCIS II recommendations, thus introducing a potential confounder.^{78,109} The extent of augmentation, method of hemodynamic monitoring, and duration of treatment are not characterized in the pediatric population.

The management of pediatric SCI should include placement of an arterial line and maintenance of an age-appropriate MAP. Treatment with vasopressors to elevate the blood pressure above the mean for age and height warrants further study before definitive recommendations can be made. An appropriate course of treatment would be to maintain the MAP at the 95th percentile for age and height over a 5- to 7-day period. Based on normative data from Haque and Zaritsky, assuming that both children were in the 50th percentile for height, a 1-year-old would be maintained at an MAP of 56 mm Hg, and a 16-year-old would be managed at an MAP of 85 mm Hg.¹⁰³ The successful hemodynamic support of pediatric SCI depends on a multidisciplinary critical care team in close coordination with neurosurgery.

Operative decision making in pediatric SCI revolves around instability and spinal cord or nerve root compression. The timing of surgery is determined by the degree of instability and the presence of irreducible dislocations and incomplete injuries with or without progressive neurologic deterioration. The actual timing of decompression has been the subject of medical controversy and has far-reaching medicolegal implications. Fehlings et al demonstrated in the Surgical Timing in Acute Spinal Cord Injury Study (STASCIS) that the odds ratio for achieving an improvement of two grades on the American

Spinal Injury Association (ASIA) Impairment Scale is 2.83 (95% confidence interval, 1.10–7.28) for SCI patients undergoing decompression within 24 versus 48 hours.¹¹⁰ The study included individuals past the age of 16, and there are no studies specifically looking at early decompression in children. Dimar et al reviewed 11 articles from 1990 to 2009 comparing early and late decompression.¹¹¹ The medical literature demonstrated consistently shorter hospital and intensive care unit stays, fewer days on mechanical ventilators, fewer hospital-acquired cases of pneumonia and urinary tract infection, and no increase in operative complications with early versus late surgery.¹¹¹

62.8 Rehabilitation and Outcomes

The early involvement of a multidisciplinary team is vitally important in the care of pediatric patients with SCI because patients are surviving longer. The overall mortality rate is between 2.5 and 28%.^{4,21,89,102,112,113} The wide range of mortality rates represents sampling error due to small population size, a high rate of concurrent traumatic brain injury in certain populations, and inclusion of deaths before admission. Hamilton and Myles reported a 28% mortality rate, with 89% of deaths occurring at the scene of the accident.^{113,114} They cited a pediatric-to-adult mortality ratio of 2.5:1. The cervical spine injuries of younger children tend to be more rostral, resulting in a higher mortality rate. Children involved in motor vehicle collisions have the highest overall mortality rates and the poorest outcomes.^{21,113} Public health initiatives to keep children properly restrained in motor vehicles are vitally important, as 87% of children who died of SCI were unrestrained.¹¹³ Every illustrative case within this chapter is from a motor vehicle collision in which the child was improperly restrained.

Brown et al found that the median age for nonsurvivors was 5.3 years, with 14 of 19 children (74%) sustaining a high cervical SCI.²¹ Eleraky et al demonstrated in a similarly sized study that children younger than 10 years sustained more spinal cord and upper cervical spine injuries (► Fig. 62.4). Despite a higher

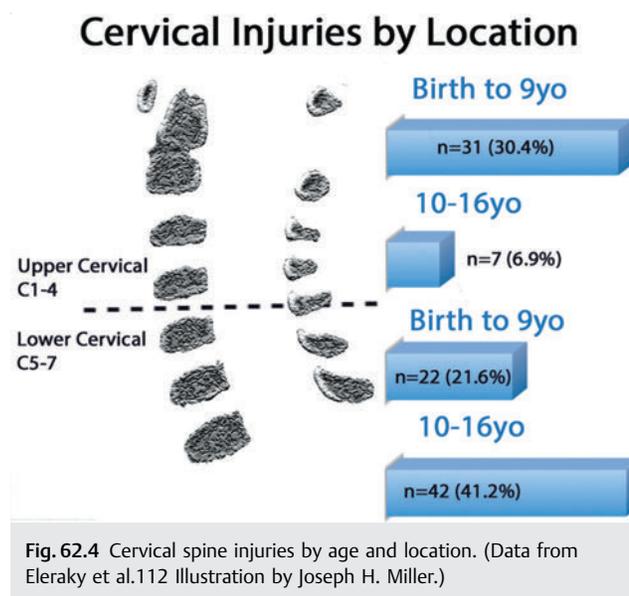

Fig. 62.4 Cervical spine injuries by age and location. (Data from Eleraky et al.¹¹² Illustration by Joseph H. Miller.)

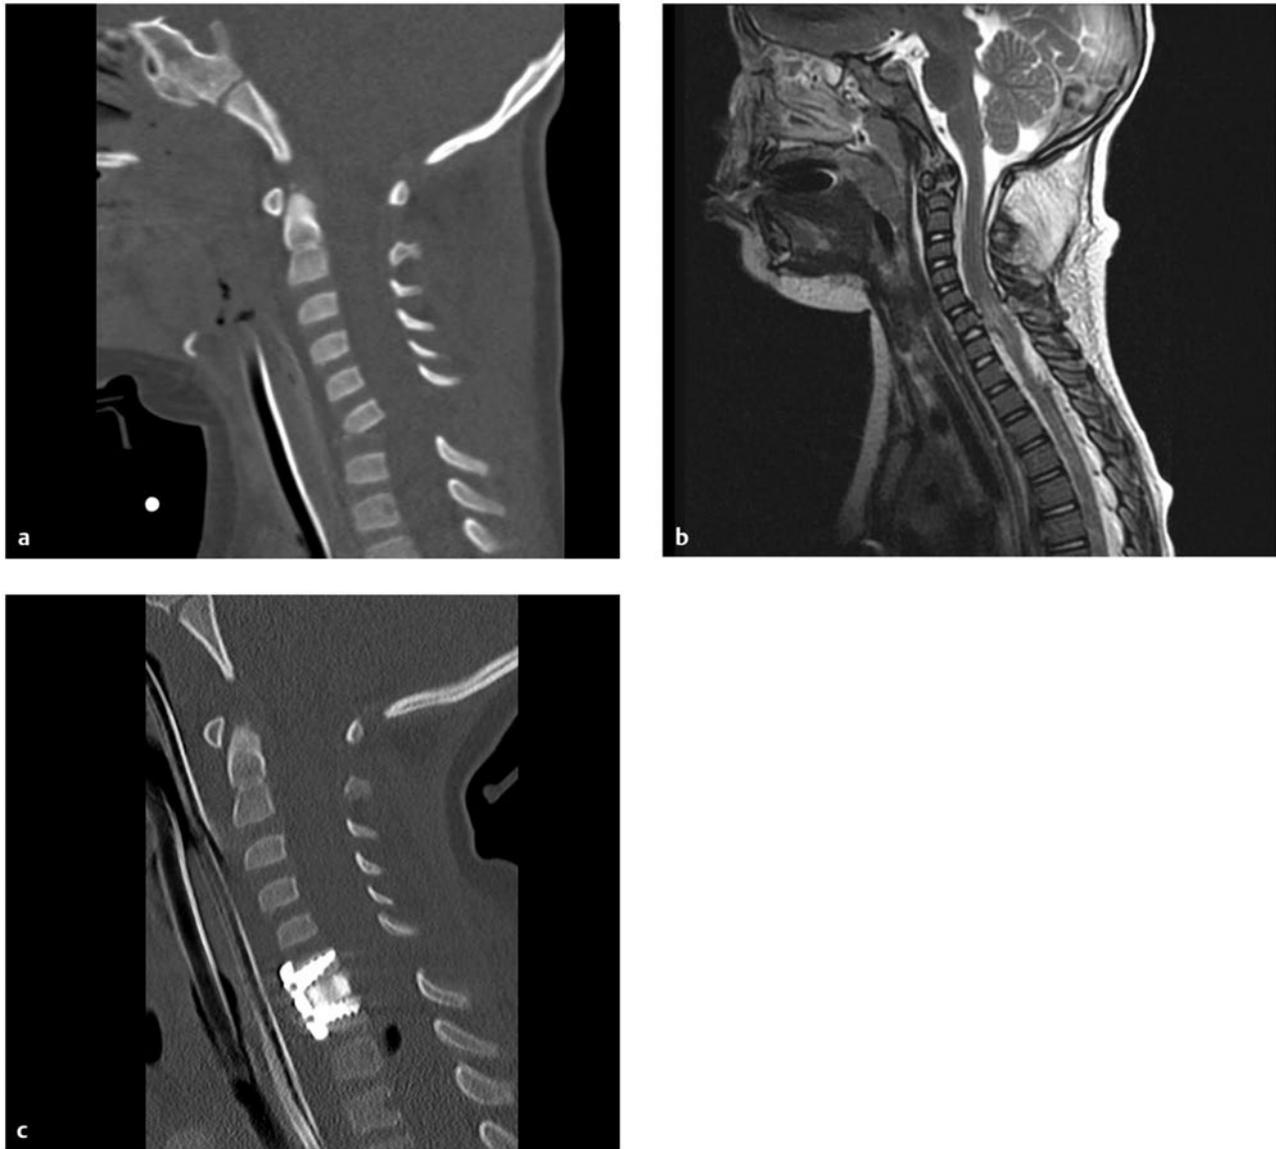

Fig. 62.5 (a,b) A 5-year-old girl after a motor vehicle collision. She initially presented with a C6 level American Spinal Injury Association (ASIA) class A injury but following anterior internal fixation/fusion (c) has improved to nearly full strength (4 + /5) in her upper extremities, including hand intrinsics. She remains weak in her lower extremities (2/5) and is unable to ambulate.

initial mortality rate than that in adults, children with SCI tend to have a more favorable long-term prognosis than adults with similar injuries.¹¹²

The NSCISC demonstrated that the life expectancy for a 10-year-old with a C5–8 cervical spine injury is 49.1 years.⁹ If that same child is ventilator-dependent, then his life expectancy is 24.1 years. The life expectancy data demonstrate that younger patients live longer because a ventilator-dependent 25-year-old has a life expectancy of only 14.9 years. Younger patients not only are living longer but also are having improved functional outcomes (► Fig. 62.5a–c).

The improvement rate of children with complete injuries (ASIA A) has been found to be as high as 35%.^{4,102} Wang et al had 20 patients who presented with complete SCI. Of these, 7 died, 7 experienced no recovery, and 6 recovered, with 5 of

them recovering to the point of ambulation.¹⁰² Factors associated with neurologic improvement were younger patient age ($p = 0.04$), SCIWORA ($p = 0.02$), and some neurologic function at presentation ($p = 0.07$).¹⁰² Eleraky et al found that in 46 patients with incomplete SCI, 38 (83%) improved completely, 3 (7%) had minimal improvement, and 5 (10%) died.¹¹² What does “minimal improvement” mean in terms of daily function? Vogel et al studied 410 adults who had experienced pediatric SCI and found that, depending on the level of injury, 28 to 39% had college degrees, 42 to 69% were employed, and 42 to 70% lived independently. Interestingly, the percentage of individuals with limited upper extremity function (C1–4 injuries) who had college degrees was higher than that in the general population. There is enormous potential for patients with pediatric SCI to live long, fruitful lives.

62.9 Complications

Short- and long-term complications that result from the initial injury or its subsequent management deserve special consideration. Pneumonia, urinary tract infections, catheter-related infections, deep vein thrombosis, pulmonary thromboembolism, and other conditions associated with prolonged hospitalization are not well characterized in the pediatric literature. These conditions are potentially preventable, as mentioned previously, with early operative intervention, and they deserve further study in children.

Complications specifically related to the spine include secondary injury, postoperative wound infections and pseudarthrosis, scoliosis, and syringomyelia. Secondary injury resulting in worsening of a neurologic injury may be prevented with appropriate prehospital immobilization, in-line or fiber-optic endotracheal intubation, and avoidance of hypotension.

The rate of postoperative complications is surprisingly low. Eleraky et al observed no complications in 30 patients and cited a 100% fusion rate.¹¹² Gluf and Brockmeyer had an 8.3% rate of wound infections, and additional studies seemed to confirm a more realistic postoperative complication rate closer to 10%.^{112,115} The risk for vertebral artery injury may be slightly higher with cervical spine screw fixation in children because the smaller lateral masses, pedicles, and pars require more precise trajectories.^{112,115} Gluf and Brockmeyer reported 2 vertebral artery injuries in 67 operative cases (1.6%).¹¹⁵ Both patients required postoperative halo immobilization, but neither had a neurologic deficit.

Instrumentation failure and pseudarthrosis are uncommon in children, but most preadolescent patients with SCI will have spinal deformity. Younger patients have a higher rate of developing scoliosis because of a lengthening torso and the adolescent growth spurt.⁸ According to Dearolf et al, scoliosis

will develop in 97% of preadolescent patients with SCI, whereas deformity will develop in only 52% of postadolescent patients.¹¹⁶ The method of initial fixation appears to be unrelated, and frequently follow-up is necessary to implement proper orthotic bracing. The rationale behind close follow-up is twofold: (1) bracing a patient before 10 degrees may prevent scoliosis and (2) bracing before 20 degrees may prevent the need for surgical correction⁸ (► Fig. 62.6).

The development of scoliosis or the delayed onset of a new neurologic development may be related to syringomyelia. Hadley et al, in a series of 122 patients, found a 4% ($n=5$) rate of syrinx development; all cases were in patients with a complete SCI.⁴ The development of a posttraumatic syrinx may be more likely with residual canal stenosis of more than 25% at the level of injury and focal kyphosis of more than 15 degrees.^{117,118} Complete decompression of the spinal cord at the time of initial operation, even in the setting of a complete injury, may prevent the development of syringomyelia.

Pearls

- The anatomical characteristics inherent to the developing spinal column place young children at increased risk for SCI.
- The early identification, immobilization, resuscitation, and treatment of acute SCI are crucial to recovery.
- Hemodynamic support and early operative decompression/stabilization are central concepts in the initial management of SCI.
- Children have better outcomes and longer survival than adults with similar injuries.

63 Intervertebral Disk Disease

Steven W. Hwang, Andrew Jea, and Thomas G. Luerssen

Intervertebral pathology of the pediatric spine is uncommonly encountered. The most frequent pathologies seen are herniated nucleus pulposus and diskitis/osteomyelitis, but other, less frequent diagnoses have been reported, such as inflammatory diskitis and conditions with neoplastic etiologies, such as chondrosarcoma and chordoma. Neoplastic conditions of the intervertebral disk space are extremely rare and are further discussed in another chapter. Pediatric disk pathology also includes adjacent processes that impact the disk space, such as spondylolysis and spondylolisthesis, which are further addressed in this chapter. Given the infrequent presentation of such pathology in children, diagnoses are often delayed, and a high index of suspicion should be raised to ensure a timely diagnosis.¹⁻³

63.1 Developmental Anatomy and Embryology

The embryogenesis of the spine has been well described.⁴ At about 4 weeks of gestation, mesenchymal cells migrate medially from the sclerotomes to surround the notochord and form the perinotochordal sheath. The sheath differentiates into alternating dense and loose areas; the loose areas become the vertebral bodies, and the dense areas become the disks. The notochord regresses completely within the vertebral bodies but persists in the disks until it ultimately undergoes mucoid degeneration to form much of the nucleus pulposus. The peripheral cells of the nucleus blend with the perinotochordal mesenchyme to form the annulus fibrosus. By the end of embryonic development (8 weeks), the distinction between the disks and bodies is clear, and notochord segmentation and formation of the annulus have begun (► Fig. 63.1). By 24 weeks, the end plates can be identified, and fibroblasts have begun to invade the nucleus.⁵

Both the annulus and the nucleus pulposus are well defined at birth. The annulus consists primarily of type 1 collagen fibrils. They are arranged in concentric lamellae that run

obliquely between adjacent vertebrae and attach to either the vertebral bodies or the cartilaginous end plates. The annulus also contains a small amount of proteoglycan and a few cells. The nucleus pulposus is composed mostly of type 2 collagen fibrils and a few cells embedded in a hydrated proteoglycan matrix. The proteoglycan molecules consist of a protein core studded with glycosaminoglycans. Chondroitin sulfate and keratin sulfate are the glycosaminoglycans most commonly found in the disk. The proteoglycan molecules can bind to hyaluronate to create large aggregates; aggrecan is the predominant form.⁶ Other collagen subtypes are found throughout the disk, but they occur in small quantities.^{6,7} Blood vessels can be found in the disk for the first several years of life. They disappear gradually and are absent by early adulthood.⁸

With normal aging, changes occur in the composition of both the nucleus and the annulus.^{6,8-10} These changes are thought to be due to the mechanical stresses imposed on the disk as well as the relatively inefficient provision of nutrients to the cells in the disk caused by the poor vascularity of the area. Over time, there is progressive dehydration of the nucleus, and degenerative granules develop in the fibrocartilage. There are areas of neovascularity and chondrocyte proliferation. Tears can be found in the annulus and the end plate. In addition, the chemical composition of the disk changes.^{6,10,11} The amount of proteoglycan in the nucleus decreases. The large aggregate molecules fragment, more keratin sulfate is present, collagen subtypes change, and inflammatory mediators can be detected. Interestingly, some of these changes can reliably be seen as early as 11 years of age.⁸ Such long-term changes explain, at least in part, the increasing incidence of disk disease associated with aging. Nevertheless, degenerative disk disease does occur in some young people.

There is growing evidence that genetic factors play a significant role in the development of disk disease. Patients with a positive family history are up to five times as likely as are those without to have a herniated lumbar disk before the age of 21 years.¹² Disease clustered in families has also been described.

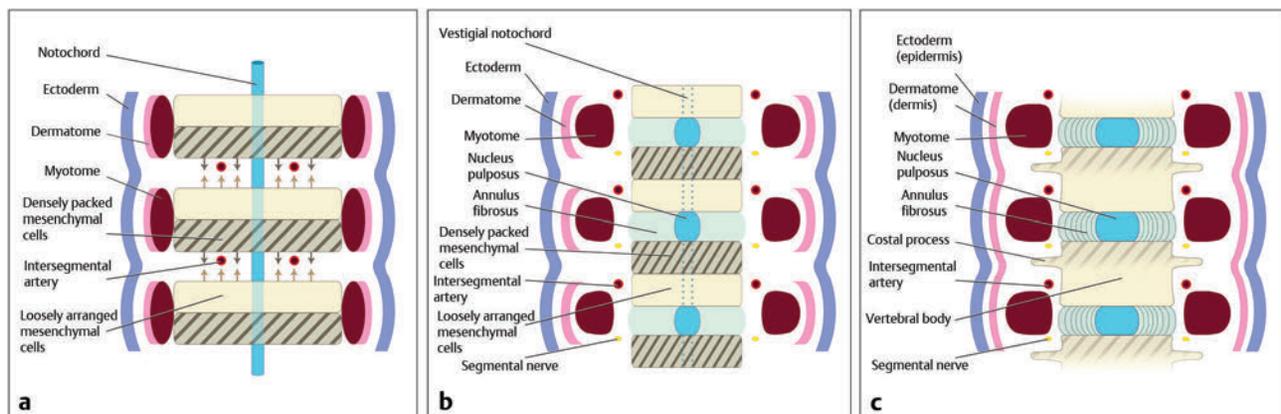

Fig. 63.1 Artist's illustration of the embryologic development of the spinal column. The somites forming the vertebral bodies divide, with adjacent rostral and caudal halves fusing to form the vertebral body and thus create the intervertebral disk space. (Printed with permission of Baylor College of Medicine.)

Scapinelli has reported eight siblings who had herniated lumbar disks; one of their parents also had disk disease. He suggested that, at least in some cases, an autosomal-dominant gene might cause disk herniation.¹³ Animal studies support this notion. Transgenic mice with mutations of the genes that produce either type 9 collagen or aggrecan have an extremely high incidence of disk disease.^{14,15} Similar findings have been reported in humans. For example, two Finnish studies reported variations in the collagen 9 alleles of persons with and without disk degeneration.^{16,17} Kawaguchi et al have described aggrecan abnormalities in patients with multilevel disk degeneration.^{18,19} In addition, variations in the gene coding for vitamin D receptor and matrix metalloproteinase 3 have been linked to disk degeneration.^{20–23}

63.2 Degenerative Disk Disease

Disk herniation is usually a pathologic process associated with degenerative disease and is assumed to be multifactorial, influenced by environmental and genetic factors.²⁴ Disk herniation also occurs in the pediatric population, but the incidence is much lower than in adults.¹ The number of cases requiring surgical treatment is 5.5 per 100,000 person-years in the population less than 25 years old, compared with 128 cases per 100,000 person-years in the 40- to 45-year-old age group.²⁵

63.2.1 Clinical Presentation

The clinical presentation of lumbar disk herniation in children is similar to that described in adults; common symptoms, in up to 50% of patients, include lumbar radiculopathy out of proportion to low back pain and motor and/or sensory loss^{1,26–30} (► Fig. 63.2). However, it is not clear that the findings in adult disk herniation can be applied to a similar management strategy in the pediatric population because the structural properties of disks and environmental exposures differ between children and adults.^{1,31}

63.2.2 Treatment

Recent reports have indicated that cohorts of adult patients who undergo surgical or conservative treatment for lumbar

disk herniation exhibit similar long-term outcomes, but the outcome is unknown in children because the treatment has not been studied in the pediatric age group.³² In the largest series of pediatric patients undergoing lumbar microdiscectomy to date, Cahill et al¹ noted that although pediatric patients may not respond as well to conservative treatment as adults do, a significant proportion of them still do respond; therefore, one should attempt conservative therapy before considering surgery unless neurologic motor deficits require a more urgent operation. There have been limited reports of case series encompassing traditional open discectomy and modern microdiscectomy in pediatric patients.^{1,28–30,33,34}

Our small case series of six children³⁵ indicates that minimally invasive surgery for lumbar disk herniation in the pediatric population is a safe and efficacious procedure. The average blood loss was minimal, and the majority of patients were discharged home on the same day as surgery or the first postoperative day. The lumbar incision is about 22 mm in length, a reported cosmetic benefit. Patients are usually mobile several hours after surgery, although we limit strenuous physical activity for 12 weeks. Athletes were able to return to competitive sports after this period of activity restriction. In our series, there were no postoperative complications, including cerebrospinal fluid leak or recurrence of disk herniation; however, this may be due to the small number of patients who have undergone minimally invasive surgery and our lack of long-term follow-up.

Although there were no complications in our pediatric series, early postoperative complications reported by others in the literature include wound hematoma (1 to 4%) and delayed wound healing (3%).^{26,32,35} Postoperative infection, such as wound infection and diskitis secondary to lumbar spine surgery, is rare in children and adolescents.^{29,36,37} There have also been reports of narrowing of the disk space, foraminal stenosis, and adjacent disk degeneration after discectomy in the pediatric population, similar to results found in the adult population.^{27,37–40} Moreover, the rate of reoperation can be as high as 24% after extended follow-up.^{26,33,41}

63.3 Traumatic Disk Disease

Posterior vertebral rim fracture, a fracture of bone fragments at the posterior rim of the vertebral end plate with an associated

Fig. 63.2 (a) Midsagittal and (b) axial magnetic resonance images of the lumbosacral spine show a central disk herniation at L5–S1 associated with a “black” degenerated disk.

Fig. 63.3 (a) Midsagittal computed tomographic scan of the lumbosacral spine shows an L1–L2 apophyseal ring fracture associated with disk herniation. (b) Midsagittal and (c) axial T2-weighted magnetic resonance images of the lumbosacral spine demonstrate L1–L2 disk herniation and significant lumbar canal stenosis.

disk herniation, has been given several names: posterior marginal node; limbus fracture; fracture of the vertebral rim, ring, or end plate; epiphyseal dislocation; and apophyseal ring fracture^{42–49} (► Fig. 63.3). The mechanism of vertebral end plate fractures is not completely known. However, most authors have postulated that the pathogenesis of these fractures is trauma or strenuous physical activity.

63.3.1 Clinical Presentation

Young patients may present with a back injury⁵⁰ associated with disk herniation. The intervertebral disk is attached to the end plate by Sharpey fibers, and the end plate is separated from the remainder of the vertebral body by a cartilaginous growth plate that is replaced by bone only at 18 to 25 years of age. After the apophyseal ring of the end plate ossifies in the immature spine (typically between the ages of 10 and 15 years), this cartilaginous junction is relatively weak and susceptible to compressive and tension stresses.^{51,52} Disk herniation through the cartilaginous plate and fracture or fragmentation of the ring apophysis can occur together in response to shearing or recurrent stress.^{53,54}

Conventional X-rays and/or computed tomography (CT) may define the bone fragment, associated disk herniation, vertebral defect, and the severity of underlying spinal stenosis.^{53,55,56} Magnetic resonance (MR) imaging may also show the avulsed fragment and a defect in the posterior vertebral rim. Associated disk degeneration and herniation are usually present, and the spinal canal may be stenotic.^{54,55,57} The Epstein classification⁵⁵ of posterior vertebral rim fractures, although seldom applied, demonstrates the range of radiographic appearances of these injuries. Type I fractures are simple avulsions of the posterior cortex of the end plate; they are so thin that no obvious defect is present in the vertebral body, although an arcuate fracture fragment is visible. Type II fractures are similar in position but include medullary bone and a defect in the vertebral body. Type III fractures are small and lateral. Type IV fractures run the full height of the vertebral body and extend to both vertebral end plates^{50,55} (► Fig. 63.4).

The differential diagnosis includes ossification of the posterior longitudinal ligament, disk calcification, osteophyte formation, and disk herniation. The most important diagnostic features are the vertebral defect and the bone fragment.

This condition usually affects patients in adolescence and early adulthood, with a male-to-female ratio of 2:1.⁵⁵ The true incidence of end plate fractures associated with disk herniation

remains unknown, but the condition is increasingly becoming recognized.⁵⁸ Vertebral rim fractures may be asymptomatic. Symptomatic patients may initially present with back and leg pain, reduced lumbar movements, and restricted straight leg raise, similar to adolescents with disk herniation; motor and bowel and bladder dysfunction are usually late findings.^{53,55,56} Older adult patients may present with neurogenic claudication due to pre- or coexisting lumbar stenosis.⁵⁵

63.3.2 Treatment

Not all patients with a posterior vertebral rim fracture require surgery. In a series of 21 patients,⁵⁹ 57% responded well to conservative treatment. However, if a patient has symptoms of radiculopathy or neurogenic claudication, the treatment of choice has been discectomy with removal of the fracture fragments.^{42,55} In this case, the standard discectomy exposure may not allow adequate removal of the fracture fragments or decompression of the spinal canal, increasing the risk of surgery. Based on our experience, we advocate simple decompressive laminectomy alone to treat pediatric patients who have

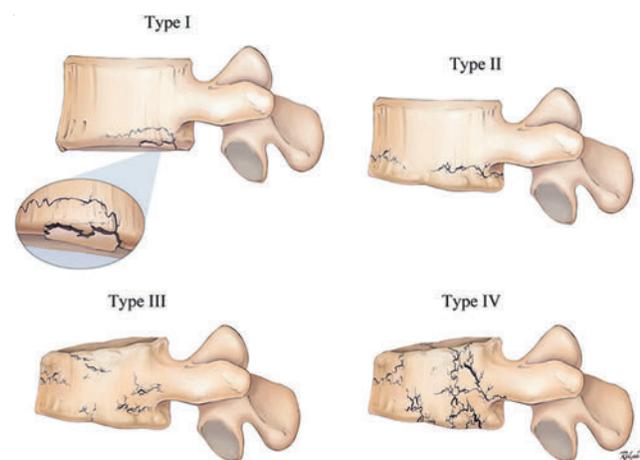

Fig. 63.4 The Epstein classification of posterior vertebral rim fractures. Type I fractures are simple avulsions of the posterior cortex of the end plate—so thin that no obvious defect is present in the vertebral body, although an arcuate fracture fragment is visible. Type II fractures are similar in position but include medullary bone and a defect in the vertebral body. Type III fractures are small and lateral. Type IV fractures run the full height of the vertebral body and extend to both vertebral end plates.

neurogenic claudication associated with posterior vertebral rim fractures. Our patients experienced good relief of preoperative symptoms and a satisfactory functional outcome. Overly aggressive laminectomy that weakens the pars interarticularis and subsequently destabilizes the vertebral column should be avoided.

63.4 Inflammatory Disk Disease

Pediatric idiopathic/ inflammatory intervertebral disk calcification is an uncommon entity. It affects the intervertebral disks and adjacent vertebral body and musculoligamentous structures, resulting in local pain or sensorimotor disturbances.⁶⁰ The etiology of pediatric idiopathic/inflammatory intervertebral disk calcifications is unknown, although associated fever, pain, and stiffness suggest an inflammatory condition. The clinical course is usually benign and self-limited, with the fever and pain resolving spontaneously within weeks or months^{61–71}; calcification of the disk space is seen at the end of the inflammatory phase.

63.4.1 Clinical Presentation

A recent review⁷² of pediatric idiopathic/inflammatory intervertebral disk calcification found a male predominance (male-to-female ratio of 8:5). Most patients are between 5 and 12 years of age. The lower cervical spine is most frequently affected, with 50% of the cases of intervertebral disk calcification occurring in the cervical spine.⁶⁵ In particular, almost all patients with cervical lesions (99.8%) are symptomatic, whereas all patients with lumbar lesions are asymptomatic.

Abnormal levels of inflammatory markers are found in half of the patients who undergo laboratory examination. The erythrocyte sedimentation rate (ESR) is the most sensitive indicator, elevated in more than 90% of patients. Considering also that more than 70% of symptomatic patients had muscle pain, an inflammatory etiology for pediatric idiopathic/inflammatory intervertebral disk calcification seems likely.

63.4.2 Treatment

In a review of the literature with more than 300 reported cases of pediatric idiopathic/inflammatory intervertebral disk calcification, only 7 patients were treated with surgery.^{71,73–77} Most surgically treated patients had a good outcome except for 1 patient with a permanent neurologic deficit.⁷⁵ On the other hand, all patients who were treated conservatively showed good functional outcome. Neither the surgical indication nor the purpose of surgery has been established in the treatment of pediatric idiopathic/inflammatory intervertebral disk calcification. Nerve root or spinal cord compression by a calcified disk may not be considered an absolute indication for surgical intervention.⁷⁸ Conservative management seems to be the mainstay of the treatment for pediatric idiopathic/inflammatory intervertebral disk calcification except in the uncommon patients presenting with acutely progressive and severe neurologic deficits.⁶⁰

63.5 Spondylodiskitis/ Osteomyelitis

Pathogens commonly encountered in children include *Staphylococcus aureus*, followed by *Streptococcus pneumoniae* and *Salmonella* species.^{2,79} Although various hypotheses of trauma and inflammation have been proposed, disk space infection is commonly thought to arise from infection at a prior site that has spread via three possible routes: hematogenously, by direct inoculation, or by direct extension. Almost 50% of children will have had a prodromal illness related to their disk space infection,⁸⁰ and immunosuppression is a reported risk factor. In children, blood vessels are present in the annulus fibrosus, and the vessels within the vertebral body typically are anastomotic, but as in adults, there are no vessels or lymphatics within the nucleus pulposus. These anatomical variations have been proposed as a reason for the preferential localization of bacterial infections to the intervertebral disk space.

Spondylodiskitis is less commonly encountered in children than in adults and has a bimodal distribution (0 to 2 years and older than 10 years). It affects mainly the thoracic and lumbar spine.^{79–81} Diagnosis can often be delayed up to 4 to 6 months as a consequence of the low incidence and vague presentation in children.^{2,3} Most commonly, children present with back pain, but nonspecific symptoms are often the only presentation, frequently without fevers. Very young children with diskitis often may refuse to walk, show regression of ambulatory motor skills, display the Gowers sign, or refuse to sit.^{82,83} Several authors have proposed categories of symptoms for children presenting with diskitis: back pain, hip and leg pain, meningeal symptoms, abdominal symptoms, and “irritable child” syndrome.^{81,84} If epidural extension is present, children may present with neurologic compromise as well.

Laboratory values (complete blood cell count, ESR, C-reactive protein [CRP]) and blood cultures should be routinely obtained, but they are often normal or only mildly elevated.⁸⁰ Blood cultures will often be positive early in the course of the illness, but given the delay in diagnosis, often only 50% are diagnostic. Very early in the course, plain radiographs may be negative because it typically takes 2 weeks to a month before disk space narrowing becomes apparent.³ The initial evaluation should include MR imaging of the entire spine with contrast. Both MR images and bone scans will reveal the abnormality, but MR imaging generally demonstrates the problem somewhat earlier.⁸⁵ Technetium 99 bone scans will identify the problem 7 to 12 days after the onset of symptoms but are nonspecific, and distinction between inflammatory and neoplastic processes is required.^{86,87} Given the vascular supply in the pediatric spine, bacterial infections typically involve the disk space, and the isocenter of the infection can often be localized to the intervertebral disk space. If the disk spaces appear relatively preserved or uninvolved, concern for tuberculous infection should be raised⁸⁸ (► Fig. 63.5).

In the pediatric population, the treatment is controversial because most spondylodiskitis infections have a relatively benign course. If a pathogen is not identified, a CT-guided biopsy should be considered before the initiation of antibiotic treatment unless clinically contraindicated (declining or unstable

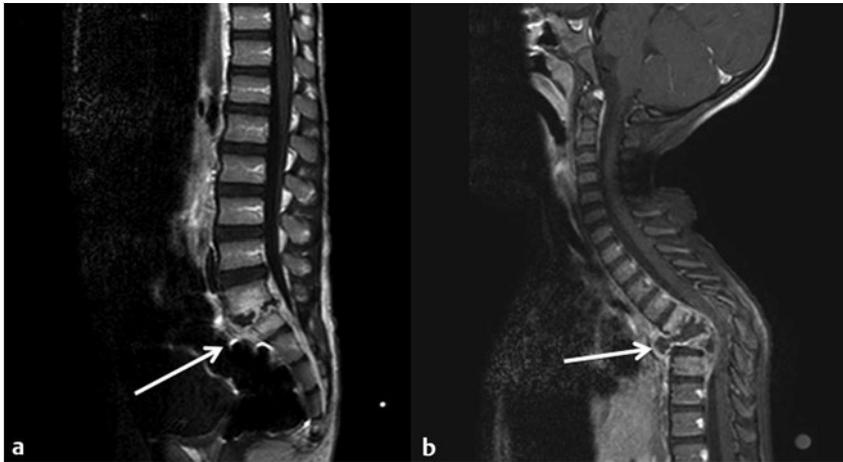

Fig. 63.5 (a) Sagittal postcontrast magnetic resonance (MR) image of the lumbar spine showing a pyogenic infection centered at the disk space with epidural extension (*white arrow*). (b) Sagittal postcontrast MR image of the thoracic spine of a patient with a tuberculous infection shows relative preservation of the adjacent disk spaces but significant involvement of the vertebral bodies (*white arrow*).

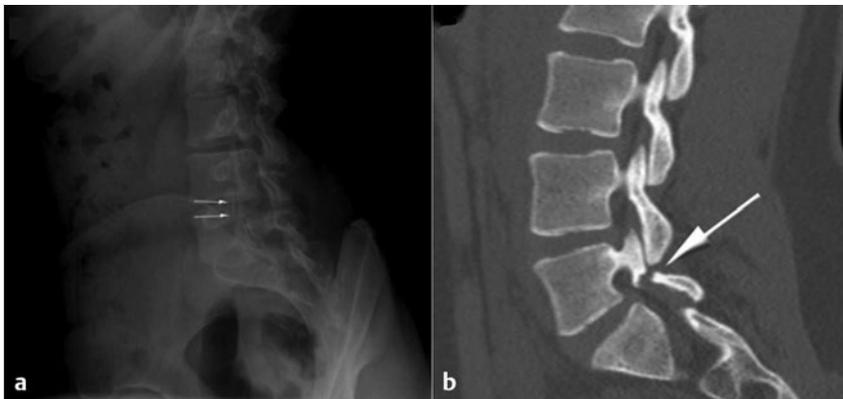

Fig. 63.6 (a) Oblique lumbar radiograph showing the pars defect (arrows) across the neck of the "Scottie dog." (b) Sagittal computed tomographic scan showing the pars defect highlighted by the *arrow*.

clinical condition). However, given the self-limiting and indolent course of the infection in children, this is also controversial; many authors will treat an infection empirically and biopsy only a refractory case. Some authors advocate no treatment with observation only because the course is often self-limiting.^{89,90} More routinely, however, a course of intravenous antibiotics followed by oral antibiotics for 6 to 8 weeks is prescribed. Given the relatively high incidence of vertebral body wedging and loss of disk space height, the adjuvant use of immobilization through a cast or brace has been proposed by some authors. Surgery can also be considered for patients with refractory and progressive infections not responding to antibiotics, but those with nondiagnostic biopsies can typically be treated with broad-spectrum antibiotics for the duration of therapy. Epidural extension with neurologic compromise should be treated with emergent decompression and evacuation of the infection.

Given the usually self-limited course, outcomes for this pathologic entity are excellent.^{79,80} Kayser et al reported 10-year or longer follow-up in 20 children and noted that 80% had no symptoms with a "freely mobile spine," whereas the remaining 20% had focal kyphosis and some restriction of spinal movement. All patients had radiographic narrowing of the disk space, and 40% had some degree of fusion across vertebrae.⁷⁹

The reported indolent and self-limiting course, as well as the high incidence of nondiagnostic blood cultures and CT-guided biopsies, may be partially due to the inclusion of nonpyogenic infections. An entity known as chronic recurrent multifocal

osteomyelitis (CRMO) or nonbacterial osteomyelitis (NBO) should be distinguished from spondylodiskitis/osteomyelitis. It is often associated with a syndrome of SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis).⁹¹ Typically, CRMO is multifocal. Patients are often healthy between episodes, with symptoms extending beyond 6 months.^{92–94} Young girls between the ages of 4 and 14 years are more often affected (5:1), but the etiology is poorly understood.^{95,96} Most patients have palmoplantar pustulosis or psoriasis. Patients may have minor diagnostic criteria of normal or mildly elevated laboratory values (CRP, ESR), hyperostosis, other autoimmune diseases, and an associated family history. Radiographic images can mimic those of osteomyelitis, but other long bones are typically involved, such as the clavicle. Bone biopsies are sterile but demonstrate evidence of inflammation and/or sclerosis or fibrosis.⁹² Standard therapy involves the use of nonsteroidal anti-inflammatory drugs, but alternate medications, such as oral steroids, methotrexate, and bisphosphonates, have been reported with positive early results.^{97–100}

63.6 Spondylolysis

Spondylolysis is to an abnormality in the pars interarticularis that is typically due to a stress or fatigue fracture. It is classified into five categories based on the presumed etiology: dysplastic, isthmic, degenerative, traumatic, and pathologic.¹⁰¹

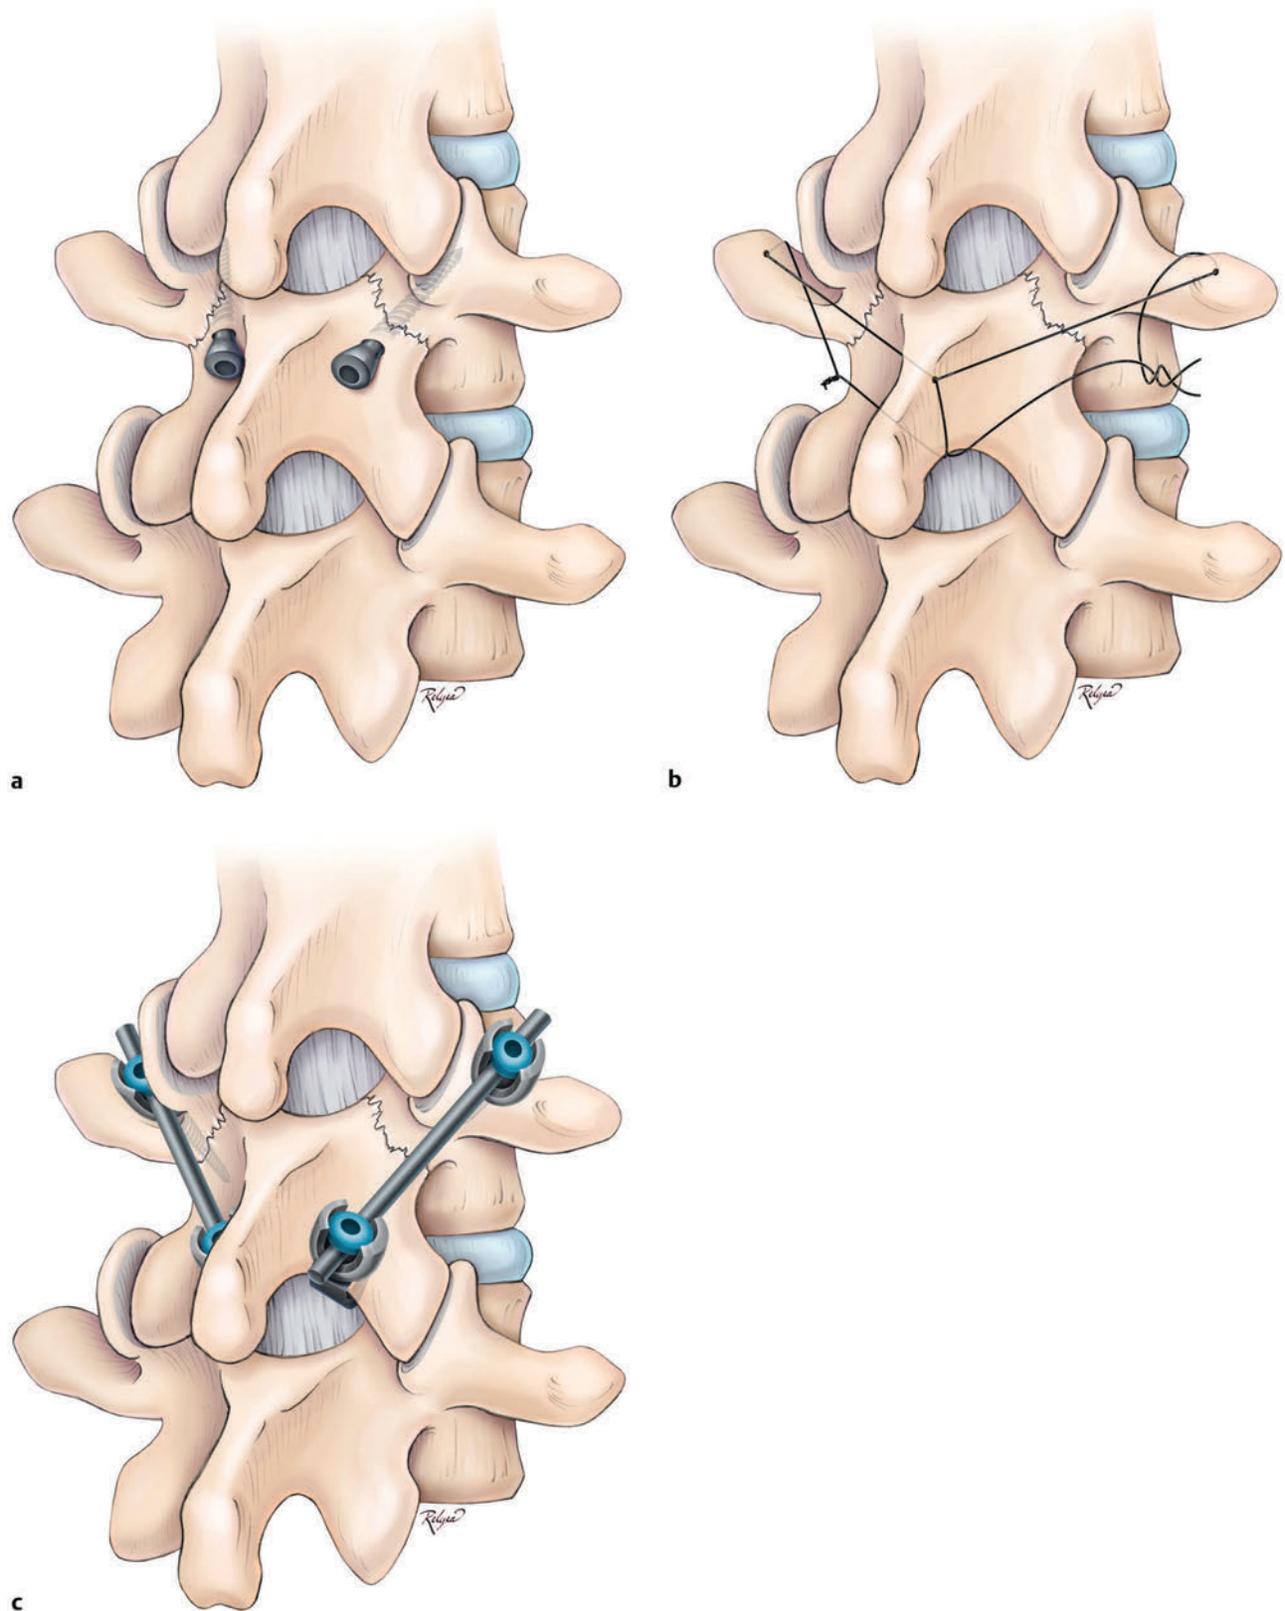

Fig. 63.7 Artist's illustration of various surgical techniques for spondylolytic repair. (a) Direct pars screw. (b) Scott's technique of wiring. (c) Laminar hook and pedicle screw construct. (Printed with permission of Baylor College of Medicine.)

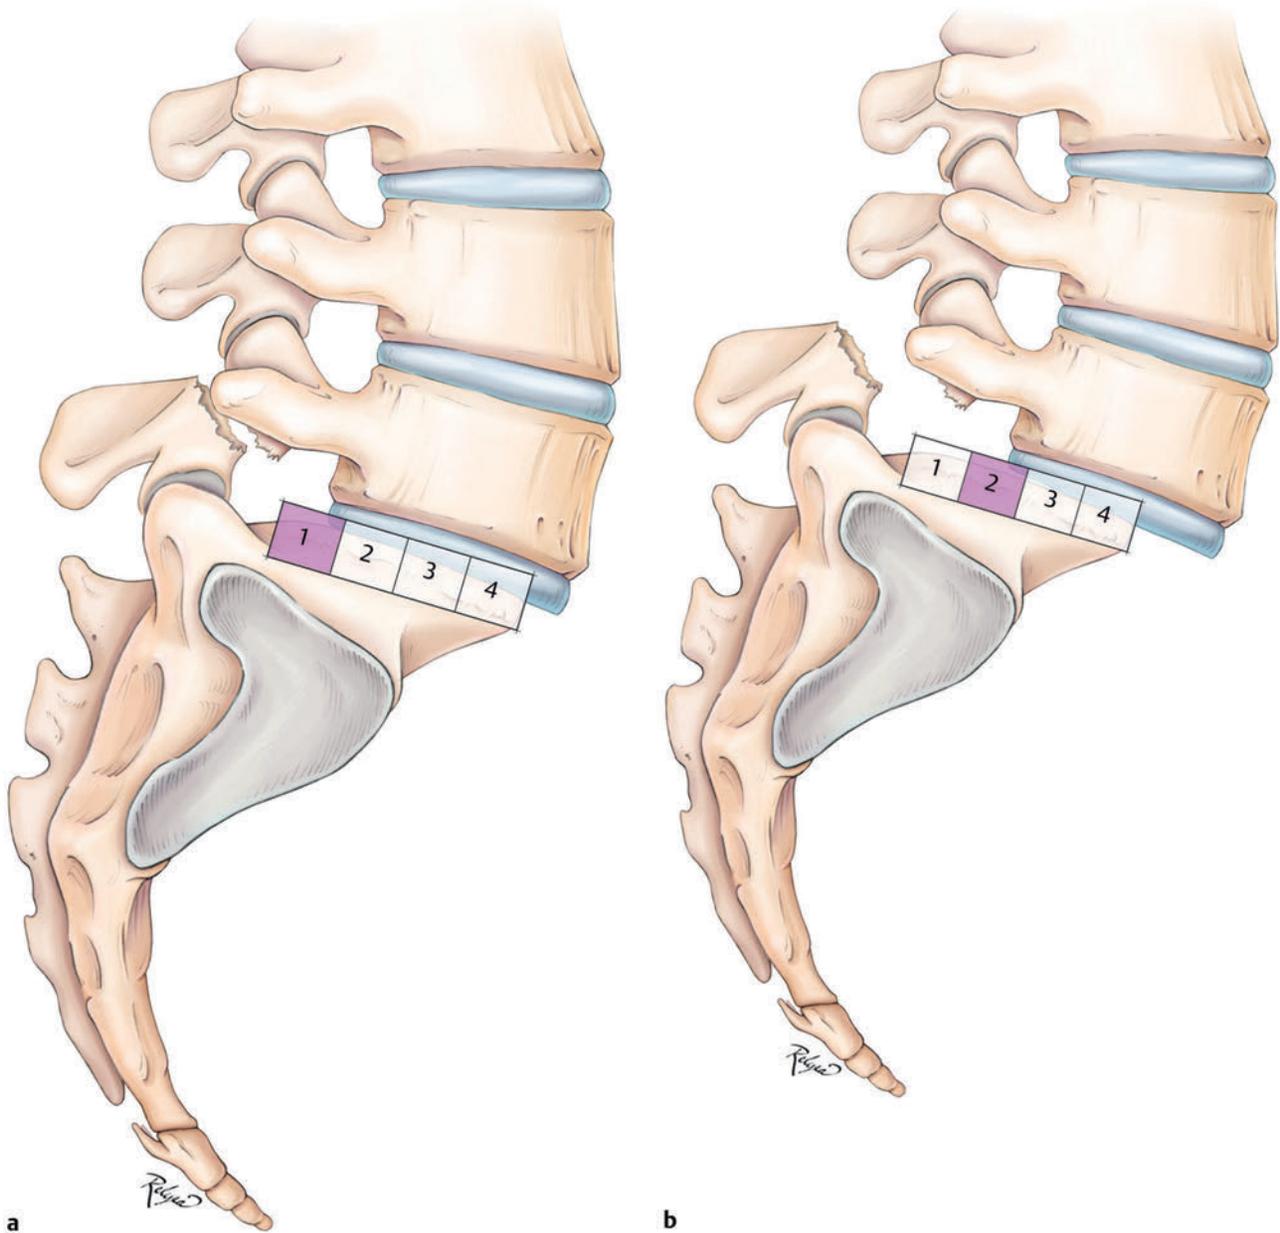

Fig. 63.8 Artist's illustration highlighting the various grades of spondylolisthesis: (a) grade 1, 0 to 25%; (b) grade 2, 26 to 50%. (Printed with permission of Baylor College of Medicine.) (continued)

The dysplastic and isthmic subtypes are most often represented in the pediatric population; dysplastic types are often associated with other osseous abnormalities and an elongated pars interarticularis, whereas isthmic subtypes are due to repeated trauma. The natural history is poorly understood, but it is generally thought to be nonprogressive. Fredrickson et al reported an incidence of 4.4% in asymptomatic schoolchildren at 6 years of age, which increased to 6% by 18 years of age.¹⁰² The increasing incidence may be related to mechanical motion and repeated stresses accrued with age. Increasing forces loaded onto the facets with hyperextension movements of the spine are believed to contribute to the development of spondylolysis. An increasing incidence (up to 47%) of spondylol-

ysis among participants in elite athletic activities such as gymnastics, tennis, diving, and weight lifting has been reported.¹⁰³⁻¹⁰⁵ Furthermore, a hereditary predisposition appears to contribute to a higher frequency among family members, but specific genes have not been identified.^{106,107}

Patients often present with low back pain after exacerbation with activity that does not resolve in an appropriate time frame. As the pathology progresses, focal hypertrophy of the synovium or an inflammatory reaction at the pars defect can develop that may extend to involve the adjacent nerve root, causing radiculopathic symptoms or signs. Patients may also have associated spondylolisthesis that may progress, further contributing to back pain.

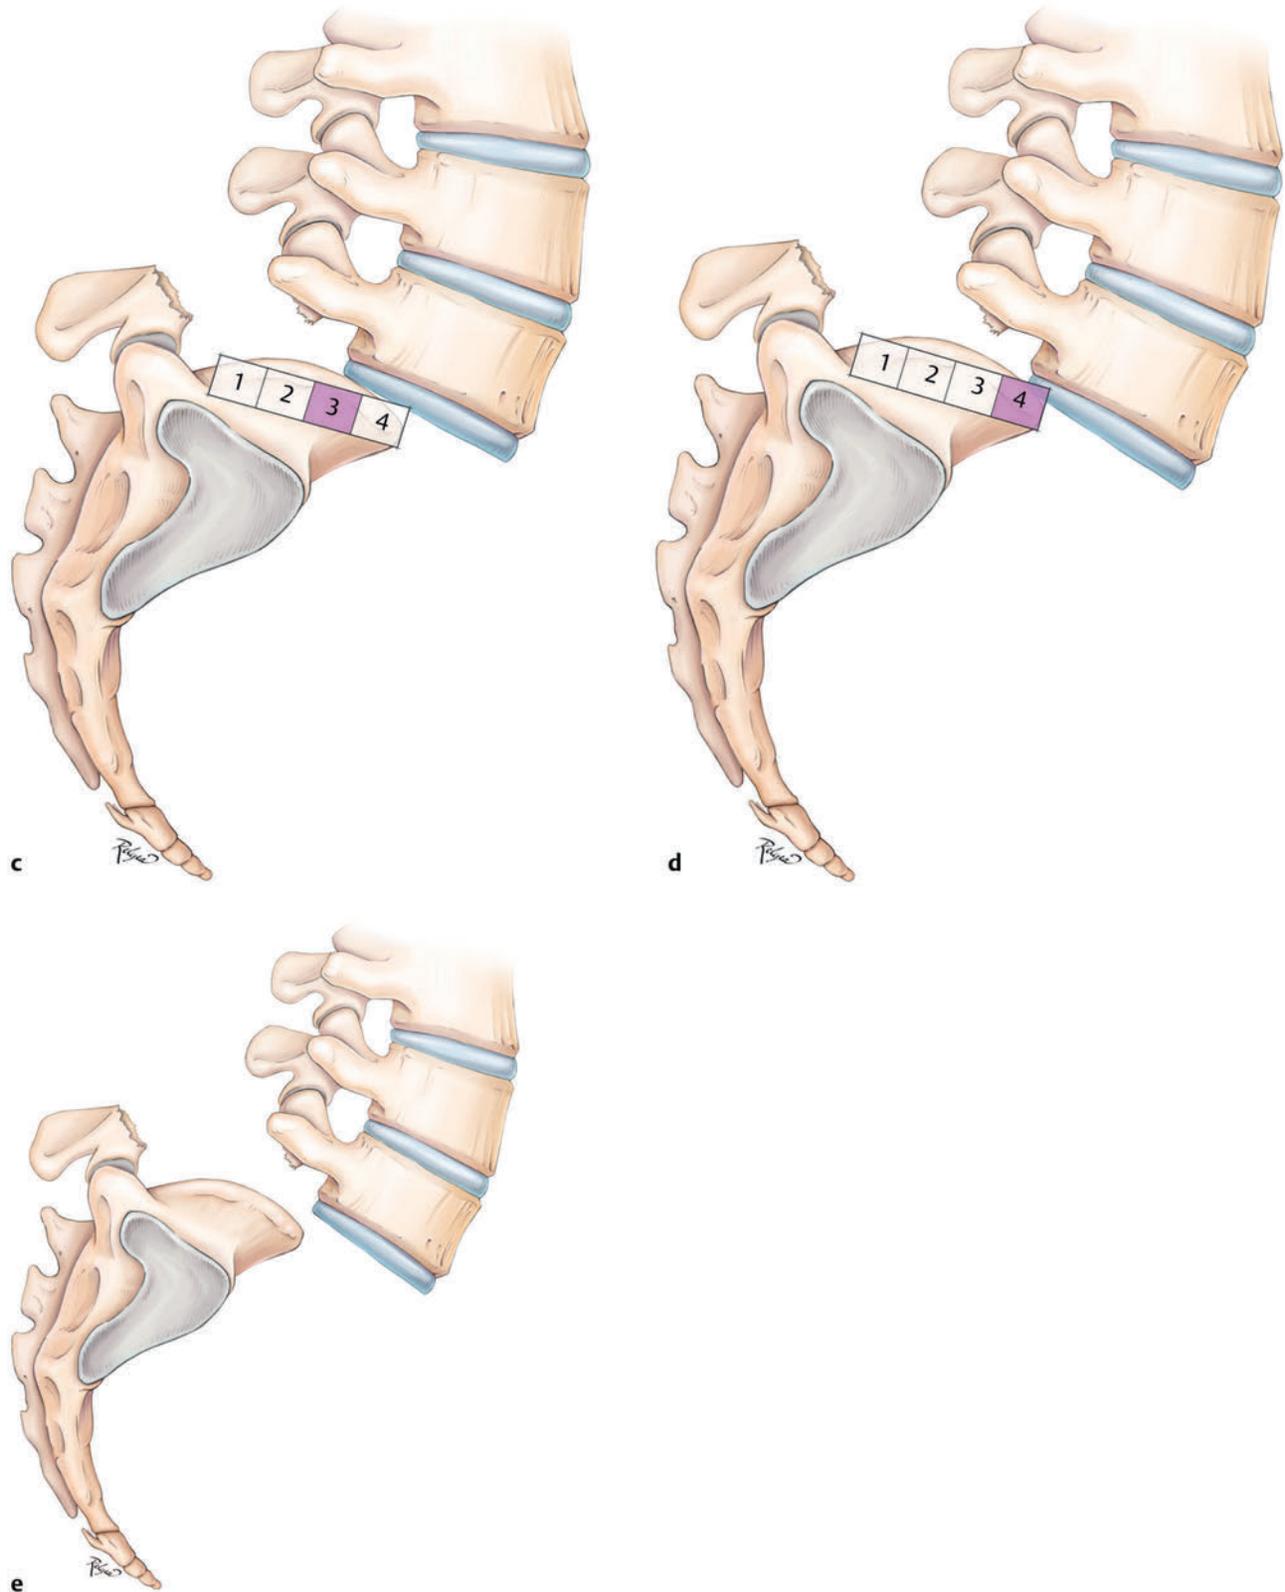

Fig. 63.8 (continued) (c) grade 3, 51 to 75%; (d) grade 4, 76 to 100%; (e) spondyloptosis, >100%.

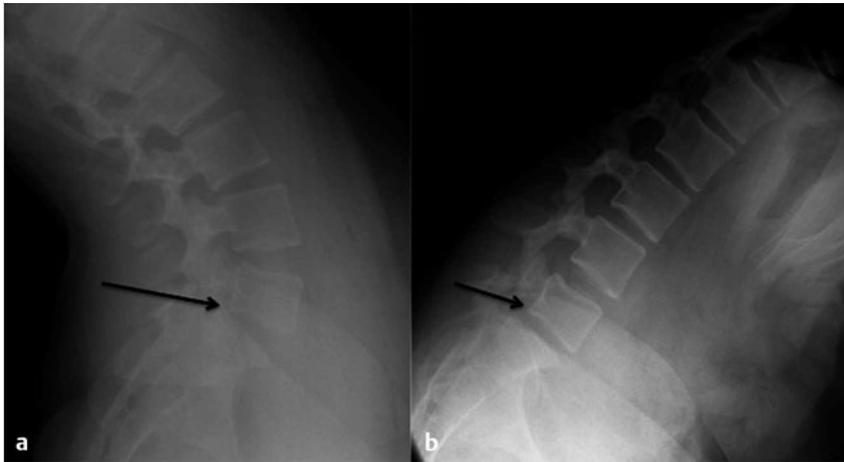

Fig. 63.9 Upright lateral lumbar radiographs showing increased movement of the vertebral bodies with (a,b) extension and flexion. The black arrows highlight the grade 1 spondylolisthesis at L5-S1.

The radiographic evaluation of a patient thought to have spondylolysis should begin with anteroposterior, lateral, and oblique radiographs (► Fig. 63.6). If only anteroposterior and lateral films are obtained, approximately 20% of defects are missed. The classic description of spondylolysis is that of La Chapelle—a radiolucency in the neck of a Scottish terrier (“Scottie dog sign”) seen on oblique views. If plain radiographs are nondiagnostic, CT of the lumbar spine is routinely then performed, followed by a bone scan. If the patient’s symptoms are long-standing (longer than 1 year), a bone scan is less likely to be useful. Read recommends single proton emission computed tomography (SPECT) for adolescents suspected of having spondylolysis because of this technique’s superior resolution and sensitivity.¹⁰⁸

Lesions that are detected early may be more responsive to nonoperative therapy, such as immobilization and rest. Particularly in the presence of stress fractures of the pars interarticularis without cortical break, early immobilization with a thoracolumbosacral orthotic (TLSO) brace with or without a hip extension has shown better results than rest alone.^{109,110} The brace is usually worn for 6 to 12 weeks until the pain resolves, and that treatment is followed by a course of physical therapy and gradual return to activity. With failed conservative therapy, several surgical options are available. Various techniques include a direct pars screw, wiring of the lamina to the spinous processes, and the construct of a laminar hook and pedicle screw connected with a rod^{111–113} (► Fig. 63.7). These techniques all bridge the pars defect and apply a compressive force across the pars with successful outcomes and fusion rates up to 100%.¹¹² Although most cases are successfully treated conservatively, excellent outcomes can be achieved for patients requiring surgical intervention.

63.7 Spondylolisthesis

Spondylolisthesis typically occurs in the setting of bilateral pars defects and appears as anterior displacement of one vertebral body on another (typically L5 on S1). It has typically been classified with the Meyerding system, in which overlap of each quarter of the vertebral body is denoted as 1 grade (i.e., 0 to 25% overlap, grade 1; 26 to 50% overlap, grade 2; etc.).¹¹⁴ Complete overhang of one vertebra over the adjacent level is termed *spondyloptosis* (► Fig. 63.8).

Patients typically present with low back pain. With severe spondylolisthesis, there may be radicular symptoms from foraminal stenosis, although compression of the cauda equina is uncommon because the posterior elements are often noncontiguous with the vertebral body. With higher-grade spondylolistheses, patients will often have increased lumbar lordosis and hamstring contractures secondary to sacropelvic parameters. Patients with severe spondylolisthesis often have a larger sacral slope (angulation between the end plate of S1 and a horizontal line) that correlates with increased lumbar lordosis. Typically, spondylolisthesis is easily seen on lateral radiographs, and the slip is often accentuated with flexion and extension views (► Fig. 63.9).

Conservative measures, such as brace immobilization and physical therapy, can be used with good outcomes for patients presenting solely with back pain and no significant instability on dynamic radiographs. Low-grade slips rarely progress over time, and most patients respond to conservative therapy.^{115–117} However, symptomatic high-grade spondylolistheses respond less well to conservative therapy, and dysplastic spondylolysis carries a greater risk for progressive olisthesis over time. Therefore, many surgeons advocate surgical management of these patients.^{118–120} In the setting of significant dynamic movement, neurologic compromise, or failed conservative therapy, surgery is necessary. Surgical intervention varies from in situ fusion to instrumented fusion with or without reduction of the spondylolisthesis (decompressive Gill procedure, transforaminal interbody fusion, posterior lateral fusion, anterior fusion, circumferential fusion, Bohlman dowel, or Gaines two-stage procedure). Typically, an attempt is made to reduce symptomatic high-grade spondylolistheses (grades 3 and 4) to restore sagittal balance and improve a high slip angle, thereby theoretically preserving function and sacropelvic parameters while minimizing the incidence of pseudarthrosis. However, management remains controversial, and even in patients with high-grade spondylolistheses, in situ fusion with postoperative bracing or casting has had comparable long-term outcomes in some series.¹²¹ The surgical reduction of high-grade slips has a higher associated complication rate, particularly with respect to pseudarthrosis and nerve root injury.¹²²

Symptomatic relief and fusion rates from approximately 70 to 100% have been reported with in situ fusion.^{118,123–125} With the use of instrumented fusion, circumferential stabilization

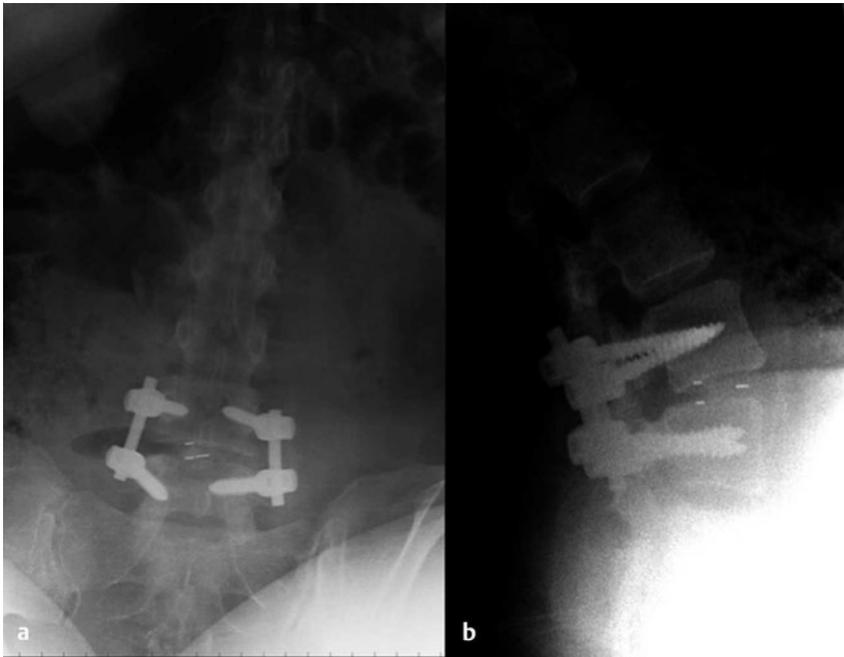

Fig. 63.10 (a,b) Postoperative radiographs showing reduction of a spondylolisthesis from a transforaminal interbody fusion (TLIF).

(anterior/posterior) has resulted in improved long-term clinical and radiographic outcomes in some series.¹²⁶ However, comparative outcomes for circumferential fusion from a posterior approach alone (transforaminal interbody fusion/posterior lumbar interbody fusion [TLIF/PLIF]) have not been well defined in the pediatric population (► Fig. 63.10).

63.8 Conclusion

Pediatric intervertebral disk pathology is uncommon. The most frequently encountered pediatric intervertebral disk pathology is herniated nucleus pulposus, which is typically seen in teenagers as they approach adulthood. Intradiskal pathology in younger children is even more uncommon. Therefore, it is difficult to determine optimal treatment algorithms in this population, given the paucity of cases reported. Management guidelines are generally extrapolated from the adult literature and may not fully apply to younger patients. Multicenter collaborations are required to help address these limitations in our understanding of such uncommon pathologic entities.

Pearls

- Intervertebral disk pathology is uncommon in children, and the diagnosis of such pathology is often delayed because of nonspecific presentations. A high index of suspicion is required to confirm many of these diagnoses.
- MR imaging is the most useful imaging modality to confirm the presence of pathology and to help distinguish among various etiologies, but it is still difficult to differentiate infection from nonpyogenic diskitis.
- The treatment algorithms for most forms of pediatric intervertebral disk disease are based on adult experience, but significant differences may exist that require further investigation for better elucidation.

64 Cavernous and Venous Malformations

Edward R. Smith and R. Michael Scott

Vascular malformations of the central nervous system (CNS) are a heterogeneous group of lesions that occur in both the brain and spinal cord. Like those in other anatomical sites, CNS vascular anomalies can be classified according to rheologic characteristics (fast-flow and slow-flow) and by channel composition (i.e., arteriovenous malformation, capillary malformation, and venous malformation) and may occur either independently or in association with syndromic conditions.

Cerebral cavernous malformation (CM) consists of compact clusters of spongelike vascular spaces without intervening neural parenchyma. The nomenclature for these malformations can be confusing as they have been called cavernomas, cavernous angiomas, and cavernous hemangiomas. *Venous malformation (VM)* is a confluent collection of enlarged veins. *Developmental venous anomaly (DVA)* is a collection of small veins converging into a dilated venous trunk. *Capillary malformation*, usually termed *capillary telangiectasia*, is usually found within the substance of the brain, especially the pons or basal ganglia; it consists of an unencapsulated collection of enlarged capillaries.

The focus of this chapter rests on CM, as the true venous malformations (DVA, VM, capillary telangiectasia) are not generally pathologic or causative of disease and, as a rule, should not be treated, although in certain circumstances they may cause headache or seizure disorders. In contrast, CMs can affect children through hemorrhage, seizure, focal neurologic deficits, and headache.

64.1 Pathology

Pathologically, CMs are a compact mass of sinusoidal vessels contiguous with one another without intervening normal

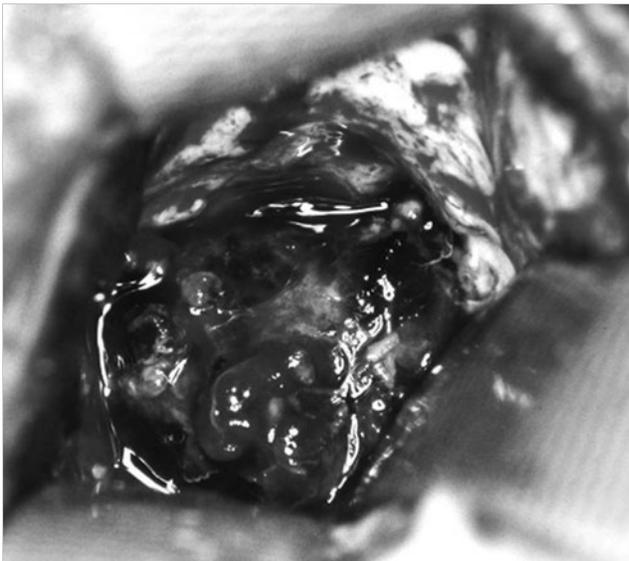

Fig. 64.1 A cavernous malformation in situ following corticectomy and linear craniotomy. The lobulated varices contain clotted and flowing blood, and the adjacent white matter is stained orange from hemosiderin from previous hemorrhages.

parenchyma. These well-circumscribed, unencapsulated masses are identified grossly as having a purple, lobulated, “mulberry” appearance (► Fig. 64.1). Calcifications may be present, both grossly and microscopically (► Fig. 64.2). Cysts containing old hemorrhage products may be present and may help explain the controversial phenomenon of growth of these lesions, providing a substrate for neovascularization following hemorrhage. Adjacent brain may be gliotic, contain focal calcifications, and frequently is stained with hemosiderin from prior hemorrhage.

64.2 Epidemiology

Most cases are sporadic (50 to 80%), although familial variants exist, with most familial cases demonstrating multiple lesions on imaging.^{1,2} Very few (approximately 10%) sporadic cases will have multiple lesions. Multiple CMs can also be found in association with cranial irradiation.^{1,3-5} CMs are found with a prevalence of about 0.5% in autopsy studies.^{1,2,6,7} A diagnostic incidence of 0.43 per 100,000 people per year has been reported.⁸ There is no difference in sex incidence.

64.3 Presentation

CMs can cause symptoms of hemorrhage or progressive enlargement with mass effect. Symptoms often depend on the location of the lesion within the CNS and can include headache, seizure, and focal neurologic deficit.⁹⁻¹² Seizure is the presenting symptom in 25 to 30% of cases. However, many CMs are asymptomatic and are frequently found incidentally.

64.4 Radiographic Evaluation

Initial studies that reveal CM usually consist of computed tomography (CT) or magnetic resonance (MR) imaging (► Fig. 64.3,

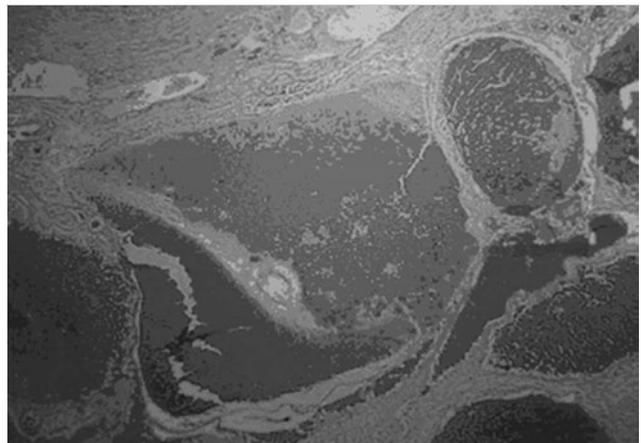

Fig. 64.2 Microscopic appearance of a typical cavernous malformation demonstrating thin-walled endothelial channels with little or no intervening brain tissue.

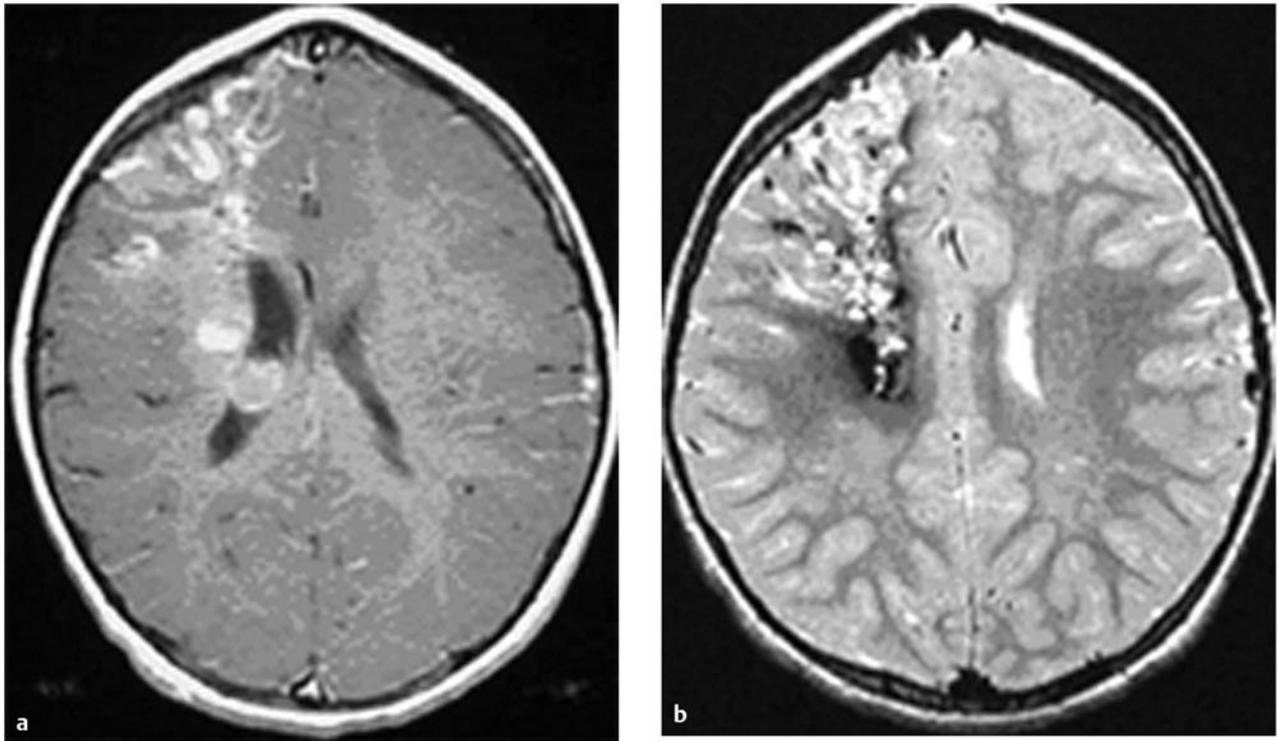

Fig. 64.3 Magnetic resonance imaging studies. (a) T1 with contrast enhancement and (b) T2 demonstrating deep right posterior frontal cavernous malformations with an overlying wedge-shaped cortical venous anomaly and telangiectasia.

► Fig. 64.4, ► Fig. 64.5, ► Fig. 64.6, ► Fig. 64.7, ► Fig. 64.8). On CT, the lesions are often well circumscribed, with hyperdense, bright foci, and blood products or speckled calcification may be present.¹³ MR imaging usually reveals a “popcorn” appearance on T2-weighted images, with evidence of hemosiderin in surrounding tissue.^{17–20} Fluid–fluid levels may be present as well. An important finding is the presence of a DVA, best seen with contrast administration and commonly manifesting the “hydra head” appearance. DVA is found in the majority of pediatric CMs, and the presence of a DVA is important for surgical planning because the prevailing teaching is that this major draining vein should be preserved at resection.^{17–20} CMs are considered angiographically occult, meaning that they are not able to be visualized well (if at all) with catheter-based angiography.²¹

64.5 Differential Diagnosis

In the setting of acute hemorrhage, other lesions, such as arteriovenous malformation (AVM), tumor, and aneurysm, should be considered. If multiple CMs are seen on imaging, the etiology may be familial or related to radiation.²²

64.6 Natural History

The natural history of CMs is difficult to predict. Annual rates of hemorrhage from CMs are about 3% for incidentally found lesions and 4 to 23% for hemorrhagic lesions.^{1,10,23–25} Some hemorrhages can be isolated, whereas others present in clusters. The usual course is an acute headache or deficit, followed by

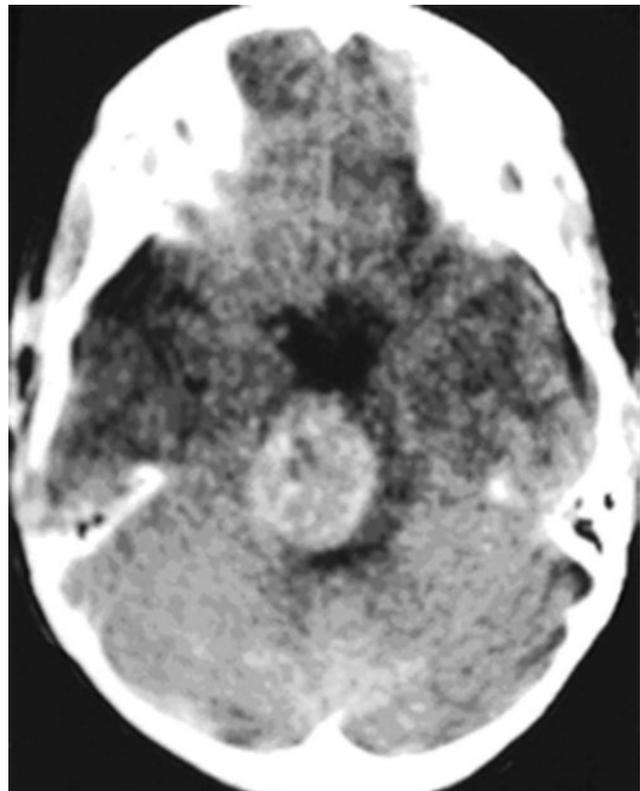

Fig. 64.4 Computed tomographic scan, unenhanced, demonstrating a massive cavernous malformation of the lateral pons and brainstem. The study shows extensive intralésional high-signal attenuation reflecting probable calcium deposition within the lesion.

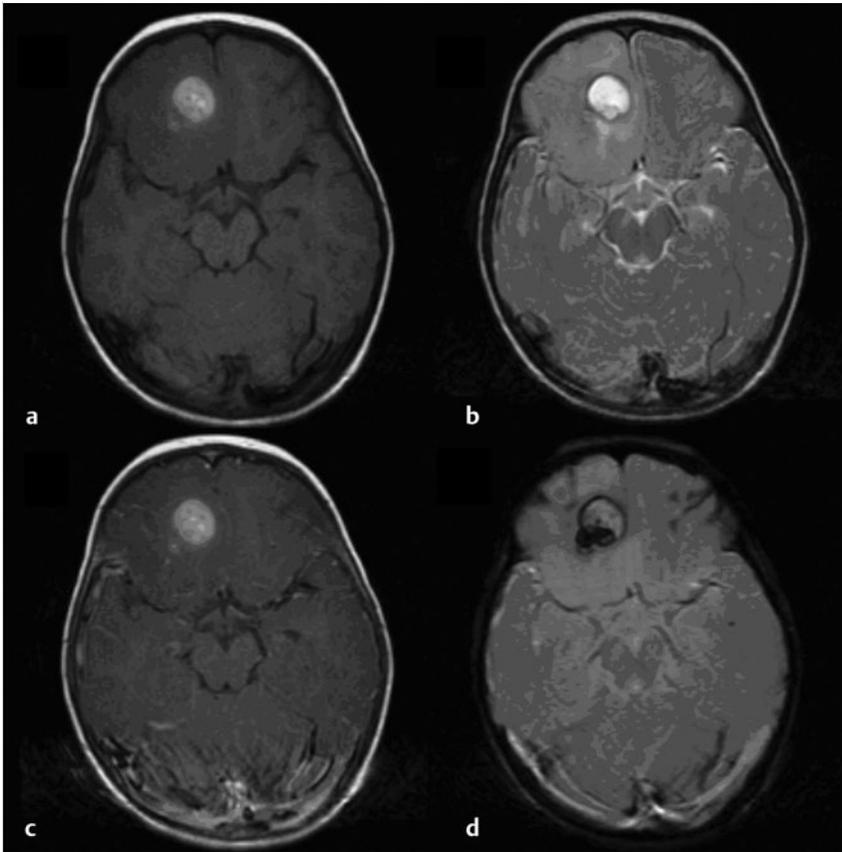

Fig. 64.5 Magnetic resonance imaging sequence. (a) T1, (b) T2, (c) T1 with contrast, and (d) gradient-echo images showing a type 1 lesion in the right frontal lobe.

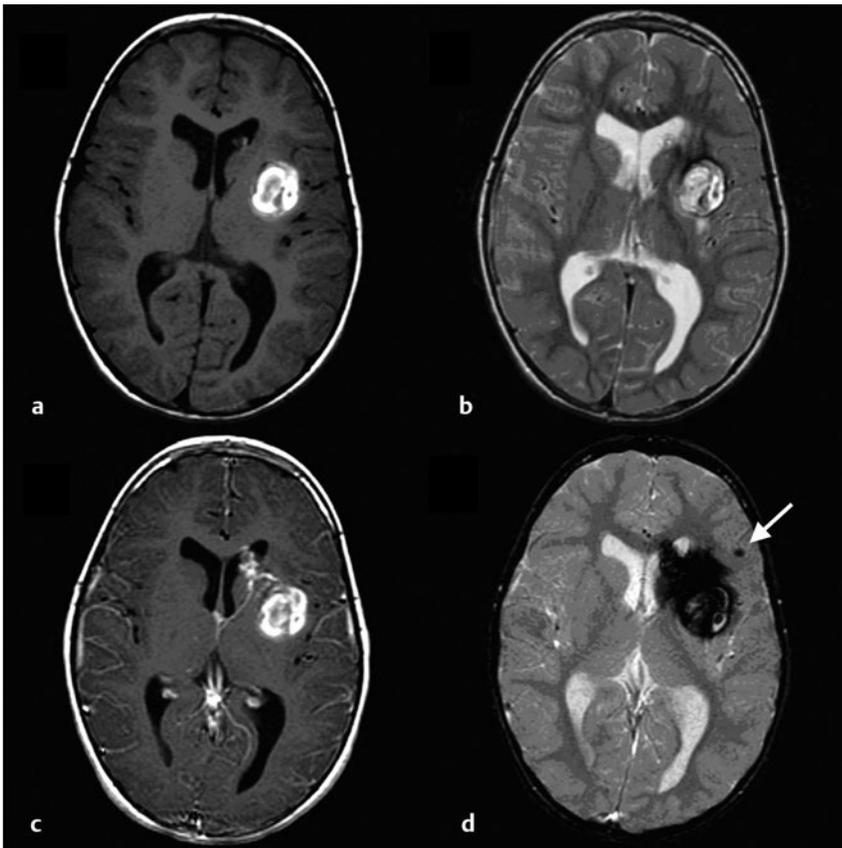

Fig. 64.6 Magnetic resonance imaging sequence. (a) T1, (b) T2, (c) T1 with contrast, and (d) gradient-echo images showing a right-sided type 2 lesion. A small type 4 lesion (arrow) is evident anterolateral to the larger type 2 lesion. In addition, a venous malformation is seen running deep to the cavernous malformation on the contrast scan.

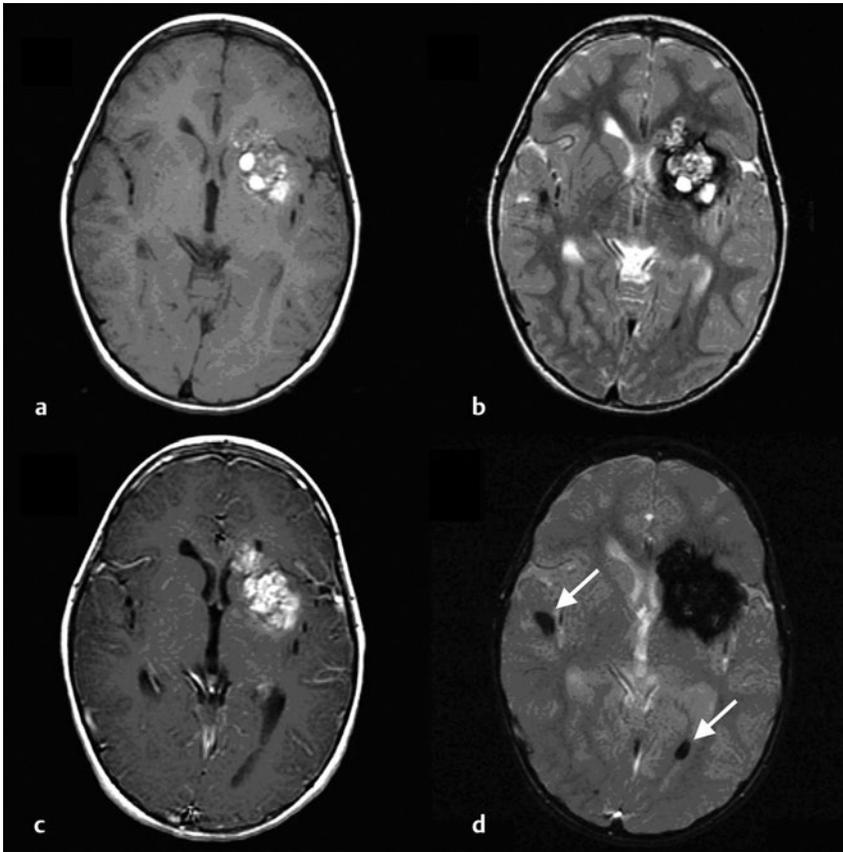

Fig. 64.7 Magnetic resonance imaging sequence. (a) T1, (b) T2, (c) T1 with contrast, and (d) gradient-echo images of the same patient as in ► Fig. 64.6 show a large type 2 lesion, with two small type 4 lesions (arrows) evident on the gradient-echo image.

slow recovery—although often not completely back to baseline—over a few months.^{19,24,26–29}

64.7 Indications for Surgical Treatment

With the natural history as noted, some authors have advocated the early treatment of CMs in children because their anticipated long life span may favor a more aggressive approach.^{12,24,30,31} Symptomatic lesions are resected when feasible. Asymptomatic lesions are more controversial.³² The decision to intervene is especially difficult in the patient who presents with symptoms and has multiple lesions. If the symptoms can be localized to a single lesion that is amenable to surgical resection, then that lesion should generally be removed.^{1,12}

Our practice is to surgically resect a single CM when it is located in non-eloquent cortex, or even in the spinal cord, if the lesion presents with symptoms, documented radiographic enlargement, or hemorrhage (usually after a minimum of about a month following hemorrhage in order to allow swelling to resolve, unless there is urgency because of significant mass effect) (► Fig. 64.9). For a lesion in eloquent cortex or in the brainstem, we commonly observe the lesion initially to determine if it manifests a pattern of recurrent hemorrhage that would justify the risk of surgical intervention. If hemorrhage recurs, then resection is considered. For deep lesions that are surgically inaccessible, we usually observe and treat symptomatically. We do not refer these children for radiosurgery because these malfor-

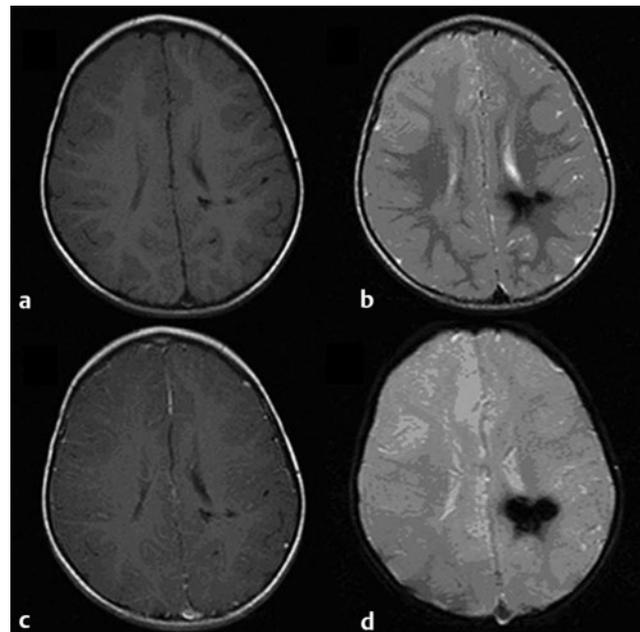

Fig. 64.8 Magnetic resonance imaging sequence. (a) T1, (b) T2, (c) T1 with contrast, and (d) gradient-echo images showing a left-sided type 3 lesion.

mations frequently react to such treatment with brain swelling and prolonged symptoms.

Referrals for genetic counseling are made for children with multiple lesions. If no lesions are symptomatic, we observe

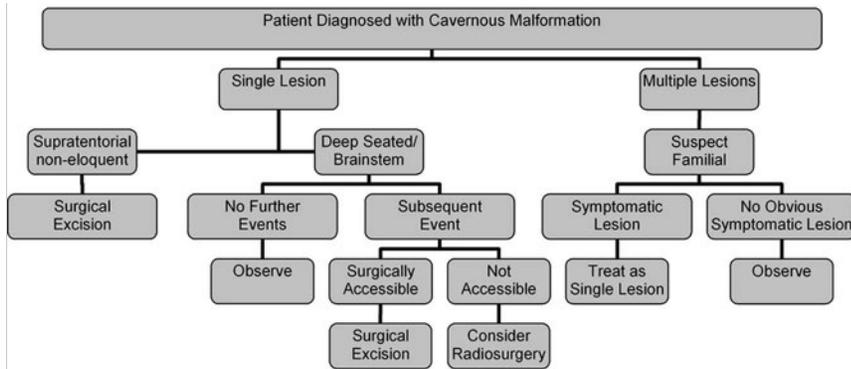

Fig. 64.9 Decision pathway for the management of pediatric cavernous malformations.

them with annual MR imaging studies. If an individual lesion grows, becomes symptomatic, or manifests new hemorrhage on imaging, then we treat following the algorithm detailed in the associated figure.

64.8 Surgical Treatment

The surgical management of CMs in children is similar to that in adults.^{1,9,32,33} In addition to the general principles of removing the entire lesion and preserving normal surrounding vasculature (especially associated DVAs), the resection of a CM may include removal of the surrounding hemosiderin ring if the lesion is cortical, associated with seizures, and in a low-risk location. In practice, the senior author (R.M.S.) rarely pursues excision of the hemosiderin as a separate strategy. In contrast, lesions in eloquent cortex, in the brainstem, or in the spinal cord should generally not have any nonlesional tissue resected in order to minimize injury to sensitive surrounding structures.

At our institution, we have routinely employed frameless stereotaxy to aid in the localization of cranial lesions. This adjunct is particularly useful for deep lesions, and we have found that placement of a catheter along the planned trajectory of approach, after the dura has been opened, is helpful as a guide to the lesion during dissection. We have also found the use of intraoperative ultrasound of immense value for real-time localization and assessment of the extent of resection. The process of resection is aided by the use of nonstick bipolar forceps and the placement of patties to maintain the plane between the lesion and normal brain. We try to avoid entering the lesion, if possible, although in some areas of the brain—particularly the brainstem—this cannot be avoided. The use of gentle coagulation on the surface can often help to reduce the bulk of the lesion while preserving integrity. The use of gentle dissection around the margins of the venous outpouchings with microdissectors will help to tease the malformation out of surrounding brain tissue and help to define dissection planes.

Of critical importance is careful inspection of the surgical cavity—preferably with the operating microscope—at the conclusion of the case. Small fragments of lesional tissue can easily be overlooked, especially if embedded in hemosiderin-stained tissue or when obscured by blood. Removal of the entire lesion will minimize the chance of postoperative recurrence.

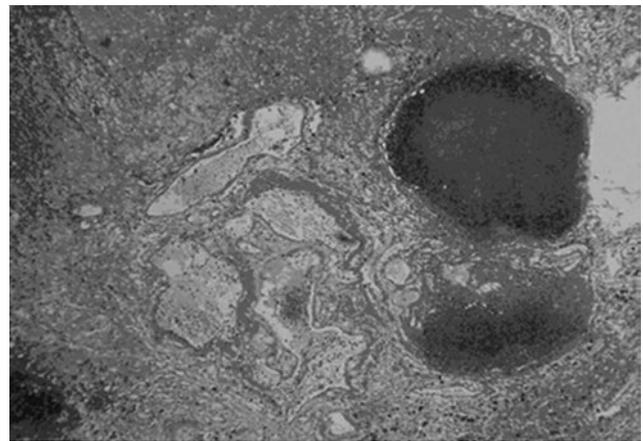

Fig. 64.10 Histologic section of a cavernous malformation that developed following radiation and chemotherapy for the treatment of acute lymphocytic leukemia. The malformation in the left temporal lobe had been treated with stereotactic radiosurgery 6 years previously and continued to bleed and enlarge. The section shows continued patency of many of the vascular channels of the malformation despite the radiosurgical treatment.

64.9 Treatment Alternatives

Radiosurgery has been used for CMs for some time, but its indications remain controversial. It is clear that CMs do not behave in the same way as AVMs that are treated with radiation. Following radiation therapy for CMs, there appears to be a temporary increase in the hemorrhage rate, in some studies up to 22.4% per patient per year³⁴ (► Fig. 64.10). Following a period of 2 to 4 years, the hemorrhage rate decreases, but the results are mixed, with rates from 0.76 to 5% per patient per year. In radiosurgery series, mortality of up to 12% has been reported in brainstem studies.^{34–36}

Morbidity varies among the series, with rates of temporary complications from 10.5 to 59% and of permanent neurologic deficit from 1.7 to 22.7%. It is generally agreed that radiosurgery should not be first-line therapy for CMs and should be reserved for inaccessible lesions that bleed repeatedly. Recent data suggest that more accurate targeting and smaller doses may improve the safety profile for radiosurgery in carefully selected patients with brainstem or surgically inaccessible lesions^{37,38};

however, another alternative is observation, with repeated imaging or clinical examination. For patients with asymptomatic lesions in high-risk surgical locations, it may be reasonable to adopt a practice of watchful waiting, with the understanding that in selected cases, active treatment may potentially carry a greater risk than nonintervention.

64.10 Prognostic Factors

It is difficult to assess the preoperative prognosis of children with CM. Rates of hemorrhage in prospective studies have ranged from 1.6 to 3.1% per patient per year.^{23,24,39} Risk factors for increased hemorrhage rates have also varied between the studies. A higher incidence of hemorrhage at presentation has been found in pediatric series, although some report no rebleeding after subtotal resection in selected cases with up to 10 years of follow-up.^{28,29,40} Some studies have found an increased risk for hemorrhage in patients with previous bleeds, with rates of 3.8 to 23% per patient per year.^{1,40} Hemorrhage rates have been reported to be increased in infratentorial and/or deep lesions in comparison with supratentorial and/or superficial lesions, but this finding may be a consequence of increased, confined neural tract density in these locations.^{24,40,41} Some series, including one in children, showed an increased risk for hemorrhage in female patients.^{10,19,42}

Life-threatening hemorrhage from CMs is less frequent than from AVMs but well documented. In one study, 43.3% of patients had a full recovery following hemorrhage, 23.3% were minimally disabled, 6.7% were moderately or severely disabled, and 20% died.²⁶ In more than 30 years of clinical experience, however, the senior author has never seen a fatality from a CM hemorrhage. Location of the CM is important; deep-seated lesions and brainstem lesions have been shown to have a higher rate of significant events, at 10.6% per patient per year.²⁴ Recovery from these lesions was full in 37% and partial in 36%, with no improvement in the remaining 27%. Children have been found to tolerate supratentorial hemorrhages better than adults.

64.11 Outcomes

Outcomes of surgical therapy have been remarkably good, with most series reporting a nearly 0% mortality rate and a 4 to 5% rate of new permanent deficits.^{27,32} It is important to note that risks greatly increase in sensitive locations, such as the brainstem; rates of new, permanent postoperative deficits range from 12 to 25%, suggesting a need to approach lesions in these areas with caution.^{28,29} CMs can recur if not excised in toto, and a generation of new lesions has been documented, particularly in the setting of radiation-induced lesions and familial cases.^{22,43}

For CMs in high-risk locations, such as the brainstem and eloquent cortex, there is controversy regarding the potential role of radiation as a possible treatment option.^{27,28,44} Radiosurgery has been reported to reduce the frequency of hemorrhage in these lesions from 17.3 to 4.5% per year.^{25,34} However, this decreased rate of hemorrhage comes at the cost of increased complications, including a 16% incidence of new permanent neurologic deficit and a 3% mortality rate.³⁴ As such, the use of

radiosurgery must be balanced against the expected natural history of the lesion. When these data are viewed from the perspective of a child's expectedly long life span and are coupled with the poorly quantified long-term risk for secondary injury from radiation exposure, resection should be considered as first-line therapy whenever possible.

Long-term follow-up with serial MR imaging should be considered. If recurrence is detected, reoperation can be curative. In addition, if seizures remain refractory to medical therapy and can be localized to the resection cavity, referral for a formal epilepsy evaluation may be warranted. In some cases, further operation (sometimes with intraoperative corticography) in order to remove residual hemosiderin can be helpful, with some reports indicating that nearly two-thirds of patients experience significant or complete seizure control after surgery.^{1,2}

64.12 Complications

The risks of surgical intervention vary between series. Mortality is generally low but has been reported to be up to 8% in one series of 100 brainstem CMs, although more than half of the deaths were felt not to be surgically related.^{24,29} Reported overall rates of postoperative morbidity in one large series showed a 20.6% rate of temporary and a 4.1% rate of permanent neurologic deficit.³² Following incomplete resection, repeated hemorrhage and recurrence are reported.

In the current series of CMs at our institution, surgical excision resulted in no mortality. Temporary neurologic worsening occurred in 13% of patients, and 5% had permanent neurologic worsening. Incomplete resection of several CMs did not inevitably result in repeated hemorrhage, and two of our cases with incomplete resection of pontine lesions have had symptom-free postoperative follow-up periods of longer than 20 years.

64.13 Developmental Venous Malformations

DVAs are among the most common cerebral lesions found at autopsy and on imaging. They are usually solitary, except in patients with familial cerebral CMs or extensive craniofacial slow-flow vascular malformations.⁴⁵ The sex incidence rates are approximately equal. These anomalies are usually found incidentally following investigations performed for an unrelated disorder.⁴⁶ The natural history of DVAs is poorly understood. Most seem to follow a benign course, and surgical treatment of these lesions is rarely indicated.⁴⁷ It has been suggested that DVAs in the cerebellar hemispheres are more prone to bleeding than similar lesions in other locations.⁴⁸

DVAs are usually discovered on CT scans. On noncontrast scans, they appear as ill-defined hyperdense lesions without calcification, edema, or mass effect; they often enhance with contrast.¹⁸ CT angiography can also delineate these lesions. MR imaging shows a characteristic abnormality—an enlarged transcerebral draining vein frequently associated with an area of increased parenchymal signal on T2-weighted images and occasionally with reduced parenchymatous signal on T1-weighted images. These lesions enhance with gadolinium and often have a "Medusa head" or "hydra" appearance because of the multiple

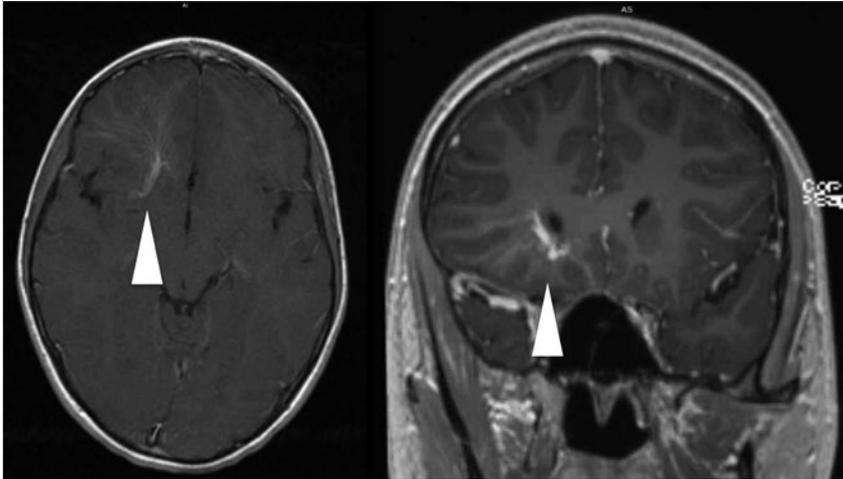

Fig. 64.11 Magnetic resonance images of a typical developmental venous anomaly (DVA), with an axial (left) and coronal (right) T1 postgadolinium sequence. The *arrowhead* in each image notes the classic DVA base with a “Medusa head.”

small veins that center around the large draining vessel¹⁸ (► Fig. 64.11). The characteristic angiographic finding is one of small, radially arranged vessels that converge on a distended vein that, in turn, is connected with the deep venous system or empties into a dural sinus.¹⁸ Frequently, the size of a DVA is inversely proportional to that of the adjacent normal venous channels.⁴⁹ For example, a large DVA in the deep periventricular white matter is typically associated with underdeveloped cortical veins and dilated transmedullary collaterals.

Surgical treatment is not indicated for DVAs. An intracerebral hemorrhage in the presence of a DVA should prompt an investigation for an associated cerebral CM.¹⁸ If a cerebral CM is to be excised, care should be taken to preserve the DVA. Occasionally, a DVA may be associated with other vascular anomalies, and one of our patients has had multiple CMs and a large arteriovenous fistula associated with a large brainstem DVA.

Pearls

- Other diagnostic entities, such as tumor, aneurysm, and AVM, should be carefully considered during the initial evaluation of a patient with CM.
- Surgery should be offered as first-line therapy for symptomatic or growing lesions in accessible regions of the CNS.
- Intraoperatively, care should be taken to maintain the integrity of the lesion if possible while avoiding injury to any associated DVA (if present).
- At the conclusion of the case, meticulous inspection of the surgical cavity—preferably with the operating microscope—is critical to reduce the risk for recurrence from an inadvertently overlooked residual lesion.

65 Moyamoya Disease

Peter A. Gooderham and Gary Steinberg

Moyamoya disease (MMD) is a chronic, idiopathic, steno-occlusive arteriopathy affecting the terminal intracranial internal carotid arteries (ICAs) bilaterally. Often, it also affects the proximal segments of the middle cerebral arteries (MCAs) and anterior cerebral arteries (ACAs), and occasionally the proximal posterior cerebral arteries (PCAs). Multiple small basal collateral vascular channels develop at the skull base and in the basal ganglia. These collateral vessels result in the characteristic appearance on angiography from which the name, moyamoya, which loosely translates to “hazy puff of smoke” in Japanese, is derived.¹ Moyamoya syndrome (MMS) has clinical and angiographic features identical to those of MMD but develops as a result of a known underlying condition, such as Down syndrome, primordial dwarfism, sickle cell disease, or neurofibromatosis. MMS may also develop following radiation treatment.² The mainstay therapy for MMD is surgical revascularization of the affected cerebral hemispheres via direct or indirect techniques.

65.1 Pathophysiology

Although MMD was first described in 1957,³ the underlying etiology of its hallmark stenosis remains unknown. There is no evidence of inflammation or atheroma on histologic examination of pathologic specimens.⁴ MMD vessels demonstrate eccentric fibrocellular thickening of the intima, proliferation of smooth muscle cells in the media, and abnormalities of the internal elastic lamina.⁴ In response to the cerebral hypoperfusion that is secondary to the steno-occlusive disease, there is increased expression of hypoxia inducible factor 1, vascular endothelial growth factor, and basic fibroblast growth factor.⁴ The increased expression of these growth factors is thought to promote the development of the multiple small basal collateral vessels. On histopathologic examination, the vessels are thin-walled, with an incomplete internal elastic lamina and reduced numbers of medial smooth muscle cells. The vessels are therefore at increased risk for the development of aneurysmal dilation and rupture, resulting in hemorrhage.⁴ The staging system of Suzuki and Takaku divides the progression of steno-occlusive disease and collateral development into six sequential stages.¹

65.2 Epidemiology

Pediatric MMD is most prevalent in Japan and Korea, with an estimated prevalence of 9 cases per 100,000 children in Japan.⁵ A recent French study found the incidence of MMD to be 0.065 per 100,000 children per year, with an overall prevalence of 0.39 per 100,000 children.⁵ MMD has a bimodal age distribution; the first peak occurs in the pediatric population (ages 5 to 9 years), and the second in mid adulthood (ages 45 to 49 years).⁶ Although its peak incidence is in children is 5 to 9 years of age, MMD can occur in children of any age, with rare cases reported in infancy.⁷ In children younger than 10 years of age, MMD occurs with equal frequency in boys and girls. In older children, MMD is much more frequent in girls than in boys, with a male-to-female ratio of 2:1.^{6,8} A family history of MMD

is identified in up to 10% of patients.⁹ Unilateral moyamoya occurs in 27 to 39% of patients with MMD or MMS.^{8,10,11}

65.3 Presentation and Natural History

Most commonly, MMD presents in the pediatric population as a transient ischemic attack (TIA) or stroke. These occur from cerebral hypoperfusion secondary to progressive steno-occlusive disease of the ICA, MCA, and/or ACA. Because of the vascular territories affected, TIA or stroke often manifests as hemiparesis, hemisensory loss, dysarthria, or dysphasia. In some cases, the deficits are nonfocal and involve failure to achieve developmental milestones or a deterioration in school performance. In the series of 143 pediatric patients with MMD and MMS reported by Scott et al, stroke had occurred in 68% and TIA in 43% of patients on presentation. Intracranial hemorrhage is an uncommon presentation of patients with pediatric MMD, occurring in 3 to 9% of patients. This is consistent across studies from Asia and North America.^{12,13} Intracranial hemorrhage is thought to be secondary to fragility and/or aneurysmal dilation of the basal moyamoya vessels. Deep intracerebral hemorrhage, intraventricular hemorrhage, or both are the most common patterns of bleeding. Subarachnoid hemorrhage has also been reported. Movement disorder in the absence of stroke or hemorrhage is a rare presentation of MMD. This is thought to be due to dilated moyamoya vessels coursing through the basal ganglia.¹⁴ These patients may present with hemiballismus or chorea. Headache and seizure are other presenting features reported in MMD. MMS found on the screening images of at-risk patients and incidentally discovered MMD are increasingly common as neuroimaging becomes more frequent and awareness of the disease becomes more widespread.

Although the natural history literature for pediatric MMD is somewhat limited, there appears to be nearly uniform progression of the disease, with a high rate of new clinical events in untreated patients. Imaizumi et al followed 15 untreated pediatric patients with MMD until adulthood. Only 4 patients in the series had a good outcome without limitations to activities of daily living, ongoing TIAs, or headaches.¹⁵ In a single-institution series of 35 patients with MMD, 7 of whom were children at the time of diagnosis, Chiu et al reported that the risk for recurrent stroke was 18% in the first year and roughly 5% per year thereafter. Results did not vary with age at presentation.¹⁶

Unilateral MMD has a high rate of progression to bilateral disease. In a series of 18 patients with unilateral MMD followed at Stanford, 39% of patients went on to develop disease in the uninvolved side over a mean of 12.7 months.¹⁰ In a series of 33 patients with unilateral MMD reported by Smith and Scott, progression to bilateral disease occurred in 30% of patients over a mean of 2.2 years.¹¹ The rate of progression to bilateral disease was more rapid in children younger than 7 years at diagnosis, with a mean time to progression of 0.9 year.¹¹

65.4 Clinical and Radiographic Evaluation

MMD should be considered in children who present with symptoms of permanent or reversible cerebral ischemia, especially if the symptoms are triggered by exertion or hyperventilation. All patients should undergo a thorough neurologic assessment, including a history and physical examination. Information regarding neurologic symptoms should be sought, as should evidence of an underlying condition that could suggest MMS. A detailed neurologic examination is essential in order to provide a baseline that can be followed through the perioperative period. A neuropsychological evaluation can help determine if developmental delay or specific functional disabilities are present.

Magnetic resonance (MR) imaging and MR angiography are the first-line investigations in children undergoing a work-up for possible MMD. FLAIR (fluid-attenuated inversion recovery) sequences effectively demonstrate any areas of old infarct, which are often located in the watershed zones between cerebral vascular territories. On FLAIR and contrast-enhanced T1-weighted images, linear cortical hyperintensity (the “ivy sign”) may be seen that is related to slow flow in cortical vessels.^{17,18} Diffusion-weighted imaging is sensitive for acute infarction. On T2-weighted sequences, the normal flow voids of the ICA and MCA are absent or diminished, and multiple small flow voids, representing the moyamoya collateral vessels, may be seen in the basal ganglia and thalamus.¹⁹

Digital subtraction angiography remains the gold standard technique for diagnosing MMD. It demonstrates stenosis or occlusion of the distal ICA with or without involvement of the proximal ACA or MCA. The collateral moyamoya vessels seen at the base of the brain give the “puff of smoke” appearance on angiography. The Suzuki staging system is based on the angiographic findings.¹ For preoperative planning, it is essential that the angiogram include selective external carotid artery (ECA) injections to evaluate the course and caliber of the superficial temporal arteries (STAs).

Perfusion imaging and assessment of the cerebrovascular reserve are an important part of the work-up and surgical decision making for patients with MMD. Multiple modalities are available for assessing cerebral perfusion, including single photon emission computed tomography (SPECT), MR perfusion imaging, BOLD (blood oxygenation level-dependent contrast) MR imaging, CT perfusion imaging, and positron emission tomography (PET). A complete discussion of the attributes of each imaging modality is beyond the scope of this chapter. However, at Stanford, we perform xenon CT or MR perfusion imaging with acetazolamide challenge for the assessment of cerebrovascular reserve in patients with MMD. All patients undergo testing as part of their preoperative work-up and at 6 months postoperatively. Although baseline perfusion imaging is informative, an assessment of the cerebrovascular reserve by means of vasodilator challenge with acetazolamide or hypercapnea provides the best predictor of the territory at risk for stroke. The normal response to vasodilator challenge is an increase in the cerebral blood flow compared with baseline values. In territories with decreased reserve, there is an absence of the normal augmentation of cerebral blood flow or even a steal

phenomenon (reduced cerebral blood flow). This occurs because the vessels are already maximally dilated. In patients with MMD, revascularization surgery is recommended for hemispheres in which an absence of normal augmentation or the steal phenomenon is observed, as either of these portends an increased risk for stroke.

65.5 Indications for Surgical Treatment

Considering the high risk for stroke or recurrent stroke in patients with MMD, surgical revascularization should be offered to all patients with MMD who have symptoms of cerebral ischemia. Surgery should also be offered to asymptomatic patients and patients who present with hemorrhage if there is evidence on perfusion imaging of reduced cerebrovascular reserve, which suggests an increased risk for future ischemic events.²⁰ Patients with unilateral MMD in whom progression on the initially unaffected side is noted on follow-up imaging should also be offered treatment if there is evidence of reduced cerebrovascular reserve on perfusion imaging.²¹

65.6 Surgical Treatment

The surgical treatment for MMD involves revascularization of the affected cerebrovascular territories. This can be accomplished via direct arterial bypass or through indirect revascularization. Direct bypass generally involves anastomosis of an STA to a cortical MCA branch. Other possible donor vessels include the middle meningeal artery (MMA) and the occipital artery, if there is no useable STA. Indirect bypass involves the application of vascularized tissue to the cortical surface of the brain after it has been stripped of arachnoid in order to facilitate the development of collateral blood supply. Commonly used techniques include encephalo-duro-arterial-synangiosis (EDAS) and encephalo-myo-synangiosis (EMS). Other techniques include dural inversion, onlay of pericranium, multiple bur holes, and free or pedicled omental transposition. In the Stanford series of pediatric patients with MMD, 162 hemispheres were revascularized in 96 patients. A direct bypass was performed in 67% of the patients, and an indirect bypass was performed in the remaining 33%. The determining factors precluding direct bypass were size and fragility of the STA or M4 segment in all cases. Indirect procedures were more common in younger children. The youngest child in whom a direct bypass was feasible was 4.3 years old.⁸

We use direct revascularization as often as possible because the immediate benefit of augmentation of blood flow to the affected territory potentially reduces the risk for perioperative infarction. If a direct bypass cannot be performed, generally because of the inadequate caliber of available donor or recipient vessels, we perform an EDAS.

65.7 Perioperative Care and Anesthesia Considerations

The major concern in the surgical management of MMD is the prevention of perioperative strokes. During the immediate

preoperative period, patients should be maintained on antiplatelet therapy, and adequate hydration should be ensured. There is some evidence that hyperventilation (or iatrogenic hypocapnea) may precipitate strokes in patients with MMD. Therefore, it is imperative that painful and fear-provoking stimuli be minimized to avoid triggering inconsolable crying before the induction of anesthesia. During the procedure, iatrogenic hyperventilation must be avoided. This is detected by monitoring end-tidal carbon dioxide or frequently measuring arterial blood gases. Throughout the perioperative and intraoperative period, careful monitoring of the blood pressure is essential, and target pressures should be at or above the patient's baseline blood pressure. After induction, all patients have an arterial line inserted, and most have a central venous catheter placed for intraoperative and postoperative monitoring and management. Intraoperative neuromonitoring, including somatosensory and motor evoked potentials and electroencephalography (EEG), is always used. All changes in potentials are communicated to the anesthesia and surgical team immediately to allow optimization of the cerebral perfusion through maneuvers like elevation of the blood pressure. Mild intraoperative hypothermia, with a goal temperature of 33°C, is employed in all cases. Although there is no rigorous clinical evidence to support the use of hypothermia for focal stroke, theoretical benefits of neuroprotection exist, prospective randomized studies have proved its benefit for global stroke after cardiac arrest and neonatal hypoxic-ischemic encephalopathy,^{22–25} and we have found it to be safe.²⁶ In cases of direct bypass, the mean arterial pressure is raised to 10 mm Hg above baseline, and EEG burst suppression is achieved with the use of propofol during the temporary occlusion of the recipient M4 branch.

65.8 Direct Revascularization with the Superficial Temporal Artery–Middle Cerebral Artery Bypass

For an STA–MCA bypass to be feasible, the donor and recipient vessels must be of sufficient caliber to allow creation of the anastomosis. The minimum caliber of the donor and recipient vessels that we anastomose is 0.6 mm, but vessels should ideally have a diameter of more than 1.0 mm. The donor vessel is chosen preoperatively based on the ECA injection of the angiogram, and the larger STA branch is used. In cases in which the STA branches are similar in caliber, we preferentially use the parietal branch because it is easier to harvest and the incision is more cosmetic. The recipient vessel is chosen intraoperatively based on direct inspection of the exposed M4 vessels.

Following the induction of anesthesia, the patient is positioned supine with a lift under the shoulder and the head turned contralaterally, so that the sagittal plane of the head is parallel to the floor. The Mayfield (Integra, Plainsboro, NJ) three-point fixation system is used in patients undergoing direct bypass to ensure stability of the head during the microanastomosis. The surface projection of the donor STA branch is marked on the scalp with a “pencil” Doppler to identify its course. We prefer to use the parietal branch of the STA. The incision line is marked immediately overlying the STA, with the proximal end anterior to the tragus of the ear. If the frontal branch of the STA is being used,

the incision is kept just behind the hairline, and the distal end is curved posteriorly to allow adequate exposure of the perisylvian region with the craniotomy. Minimal or no hair is clipped for these cases.

The donor vessel is harvested in a proximal-to-distal direction, with the operating microscope used for magnification. The overlying scalp is incised with a scalpel and standard microsurgical techniques. Littler scissors and bipolar cautery are used to isolate the STA. The vessel is isolated circumferentially, with a 4- to 6-mm cuff of fascia on either side of the vessel. Small branches are coagulated and cut, and larger branches are tied off with 4–0 ties. A length of at least 7 cm of STA must be isolated to facilitate performance of the anastomosis. At the proximal end, a short segment of the vessel is denuded of soft tissue to allow temporary clipping and flow measurements. A 1-cm-long segment of the distal vessel is also denuded of soft tissue to facilitate the anastomosis. The STA is left in continuity until immediately before the anastomosis is performed to minimize the risk for vessel thrombosis and also to allow conversion to an EDAS if a suitable recipient vessel is not available (► Fig. 65.1).

Next, the temporalis muscle is incised in a sideways-H fashion, with a cuff of tissue left superiorly to allow reapproximation, and reflected out of the way to expose the underlying skull. A 6×6-cm craniotomy is then performed overlying the sylvian fissure. Meticulous extradural hemostasis is paramount, including dural tack-up sutures, so that run-in blood will not obscure the field when the anastomosis is completed. The dura is then opened in a sideways-H fashion and the dural leaves are reflected.

The exposed cortical surface is examined to identify the largest available M4 branch to act as a recipient vessel. Sometimes, the overlying arachnoid must be stripped to expose the vessels for inspection. Positioning the surgeon perpendicular to the M4 branch makes it easier to sew both walls. Once a suitable recipient is identified, the surrounding arachnoid is opened with standard microsurgical techniques, a segment devoid of branches is identified, and a small piece of high-visibility background is passed beneath the vessel. After a 5-mm temporary aneurysm clip is applied to the proximal donor artery, the distal donor artery is cut at a 45-degree angle (fish-mouthed) to maximize the size of the anastomosis. Any remaining soft tissue is stripped off the distal end. Before the anastomosis is started, the cut-flow through the STA and the M4 branch flow are measured with an ultrasonic flow probe (Charbel Micro-Flowprobe; Transonic Systems, Ithaca, NY).

Before temporary clipping of the M4 branch, EEG burst suppression is achieved with a bolus of propofol, and the patient's blood pressure is raised to 10 to 20 mm Hg above baseline. Temporary aneurysm clips are placed on the proximal and distal M4 branch, with sufficient room left to perform the anastomosis unimpeded. For temporary clipping, specially designed Anspach-Lazic (Peter Lazic GmbH, Tuttlingen, Germany) 3-mm temporary aneurysm clips are used because they have a narrower profile and smaller size than those of standard clips. An elliptical arteriotomy, sized to match the fish-mouthed donor, is made in the recipient vessel with microscissors. Using interrupted 10–0 Monosof (Covidien, Mansfield, MA) suture, the toe and then the heel ends of the anastomosis are sutured in place. The side walls of the anastomosis are then completed. Great care must be taken to avoid catching the back wall of the vessel during suturing. After completion of the anastomosis, the M4

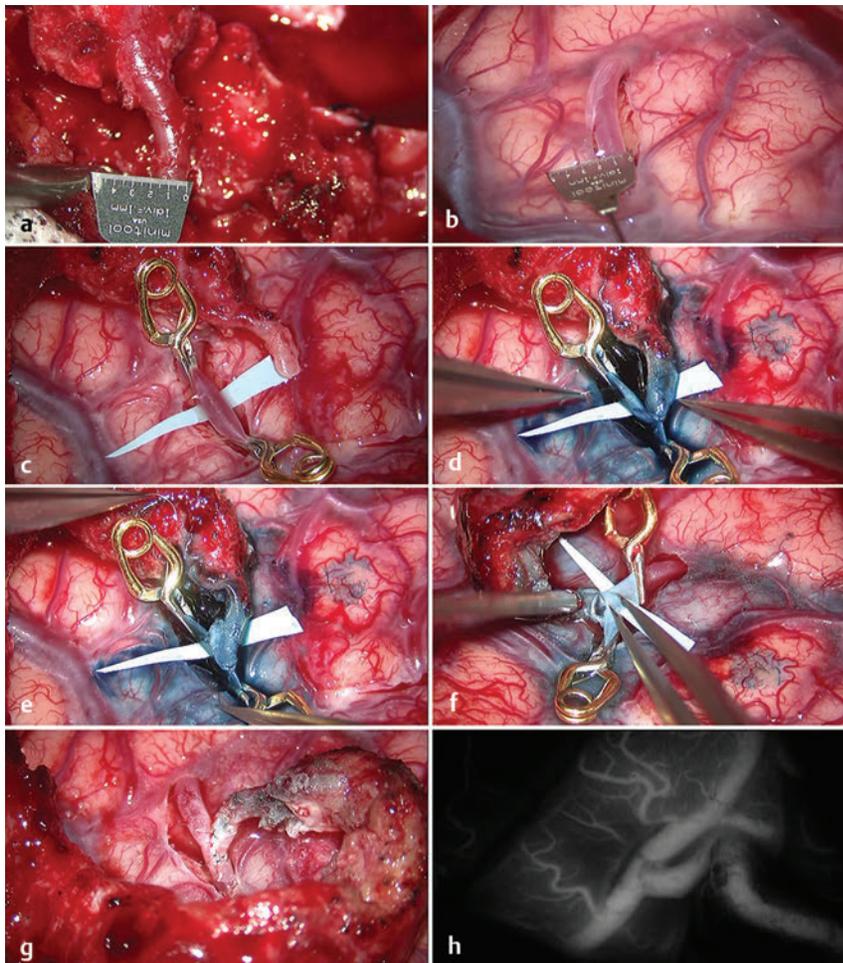

Fig. 65.1 Superficial temporal artery to middle cerebral artery (STA-MCA) bypass for moyamoya disease. (a) The minimum diameter of the distal STA or M4 for completion of an anastomosis is 0.6 mm. Ideally, the vessel diameter should be at least 1 mm. (b) After arachnoid dissection has exposed the M4 branch to be used as the recipient vessel, it is also measured to ensure adequate diameter. (c) Specially designed Anspach-Lazic (Peter Lazic GmbH, Tuttlingen, Germany) 3-mm temporary aneurysm clips are used for temporary occlusion of the recipient M4 branch. These clips have a narrower profile and smaller size than those of standard temporary aneurysm clips, which facilitate completion of the anastomosis. (d) After an elliptical arteriotomy is made in the recipient vessel, the toe of the fish-mouthed STA is sutured in place with 10-0 Monosof (Covidien, Mansfield, MA) sutures. (e) Next, the heel of the STA is sutured. This order allows tailoring of the fish mouth of the STA if there is a mismatch between the donor and recipient vessels. The side walls of the anastomosis are then sutured with interrupted 10-0 Monosof sutures. (f) After completion of the first side wall, the insides of the vessels are checked to ensure that the back wall has not been caught in a suture. (g) The completed anastomosis, with the redundant STA and fascial cuff lying on the cortical surface to allow the further development of indirect collaterals in addition to the direct bypass. (h) Indocyanine green (ICG) video angiography is used to confirm flow through the bypass.

temporary clips are removed and meticulous hemostasis is confirmed. Occasionally, additional sutures must be placed if a leak from the anastomosis occurs. Generally, this is done without repeated temporary clipping. The STA temporary clip is then removed, and hemostasis is confirmed. Flow rates in the proximal and distal M4 and STA are checked with the ultrasonic flow probe (Charbel Micro-Flowprobe), which confirms flow in each limb of the anastomosis. Very high M4 flow rates after bypass have been found to correlate with postoperative hemorrhagic and ischemic complications,²⁷ and in these cases, we control blood pressure more stringently during the postoperative period. Indocyanine green (ICG) video angiography is then performed to confirm bypass patency. The anastomosis is bolstered with small pieces of Surgicel (Ethicon, Somerville, NJ) before closure.

The dura is closed, with a defect left inferiorly to allow the STA to pass through. The bone flap is replaced with titanium plates and screws after a defect has been fashioned in the temporal aspect of the bone to allow passage of the STA without compromise. The temporalis muscle is then reapproximated again, with an opening left inferiorly through which the STA can pass. "Pencil" Doppler is used to confirm that flow in the bypass has not been compromised during closure. The scalp is closed in a layered fashion. In young children, 4-0 Monocryl suture (Ethicon) is used for skin closure. This is done to avoid inflicting pain and inducing crying during suture or staple removal, which may be associated with the induction of TIAs or strokes.

65.9 Other Direct Revascularization Techniques

When the STA is unavailable to serve as the donor vessel, such as in patients who have previously undergone cranial surgery in which the STA was sacrificed, the occipital artery or MMA can be used as the donor vessel. The ECA injection of the preoperative angiogram can be used to determine if either vessel is a potential donor. The segment of occipital artery dissected out must be long enough to rotate to the perisylvian region and bypass to an M4 branch. The MMA can be dissected from between the leaves of the dura and anastomosed to an adjacent M4 arterial branch (► Fig. 65.2).

65.10 Indirect Revascularization with Encephalo-duro-arterial-synangiosis (EDAS)

When direct revascularization is not technically feasible because of the absence or inadequate size of donor or recipient vessels, an indirect revascularization can be performed. At Stanford, we prefer the direct bypass method for its theoretical benefit of immediate revascularization, which may reduce

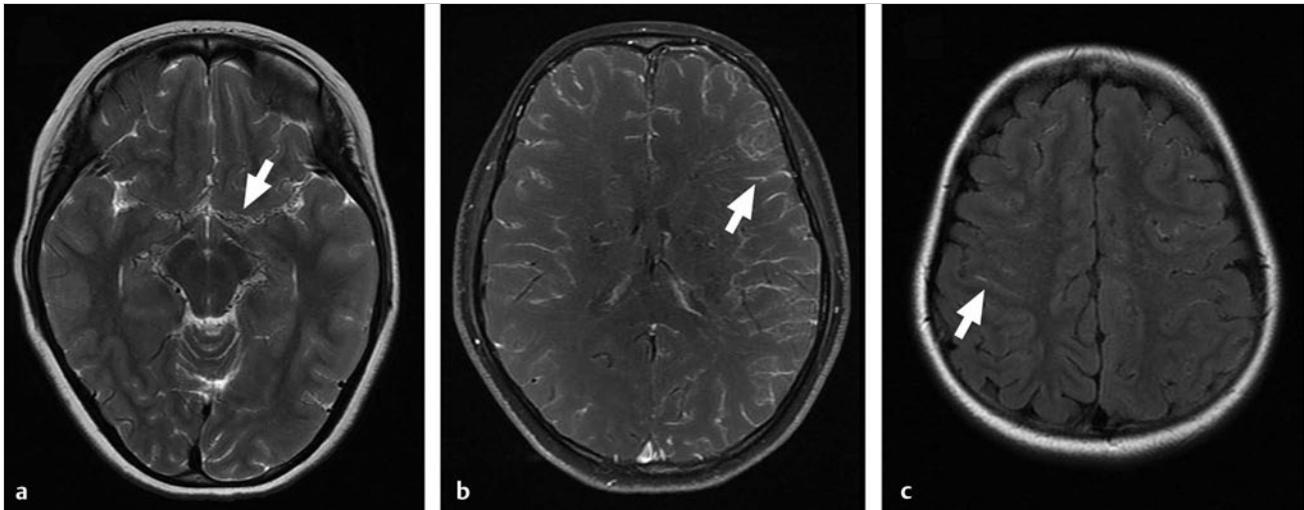

Fig. 65.2 Magnetic resonance imaging of a 10-year-old girl who presented with multiple recurrent transient ischemic attacks causing weakness of the right arm and side of the face. She was neurologically intact at the time of her assessment. T2-weighted image demonstrating multiple small flow voids in the basal cisterns (*arrow*), representing moyamoya collateral vessels (a). T1-weighted gadolinium-enhanced image (b) and FLAIR (fluid-attenuated inversion recovery) image (c) demonstrating linear sulcal hyperdensities (*arrows*), referred to as the “ivy sign,” that are thought to represent slow flow through dilated cortical vessels.

perioperative stroke rates. Other authors favor indirect techniques because they are less technically demanding and can be performed in any patient. Positioning, identification of the STA, and STA harvesting are carried out in a fashion identical to that described above for STA–MCA bypass. When the STA is harvested, a larger fascial cuff is left on either side of the vessel to maximize the surface area for the revascularization. The opening of the temporalis muscle and craniotomy are also performed as described above. It is imperative that the continuity of the STA be preserved throughout the procedure. After the dura has been opened, microsurgical techniques are used to strip arachnoid off the exposed sulci, particularly around cortical vessels. Stripping the arachnoid may facilitate the ingrowth of collateral vessels from the STA.¹³ The STA and its fascial cuff are then placed onto the exposed cortical surface. Some authors advocate using 10–0 pial sutures to secure the fascial cuff to the underlying pia for maximal apposition.¹³ The dura is closed over the STA with a patch of pericranium or Biodesign Surgisis dural graft (Cook Medical, Indianapolis, IN). Defects are left in the dura to allow entry and exit of the proximal and distal ends of the STA, respectively. The craniotomy flap is replaced after sufficient bone has been rongeuired to allow the proximal and distal ends of the STA to pass through without compromise. Closure is identical to that described above for the STA–MCA bypass (► Fig. 65.3).

65.11 Other Indirect Revascularization Techniques

In patients who lack a suitable STA for an STA–MCA bypass or EDAS, other indirect techniques may be employed. EMS with onlay of a portion of the temporalis muscle onto the cortical surface has been shown to effectively revascularize more than one-third of the MCA vascular territory in 75% of patients.²⁸

Because of the size of the temporalis muscle, the territory that can be covered with this technique is somewhat limited. When no other suitable donor tissue is available for revascularization, we have used tunneled or free omental transposition.²⁹ Multiple bur hole surgery has been proposed as a simple technique for providing indirect revascularization. Sainte-Rose and colleagues reported revascularization of 24 hemispheres with this technique (10 to 24 bur holes per hemisphere). They reported excellent revascularization in all treated patients on follow-up angiography.³⁰ At Stanford, when no STA is available for a direct or indirect graft, we have successfully used temporalis muscle or occasionally omental onlay graft. The placement of multiple bur holes or pericranial onlay grafts also sometimes achieves revascularization, although not as consistently as the other techniques.

65.12 Follow-up after Treatment

After revascularization surgery, patients undergo clinical and radiographic evaluation at 6 months, 3 years, 10 years, and 20 years after treatment. At each time point, assessment includes MR imaging, cerebral angiography, and perfusion imaging. To test for adequate revascularization, should the patient continue to have symptoms suggestive of cerebral ischemia, we undertake interim clinical and radiographic evaluation. In patients with unilateral disease, CT angiography is performed annually to check for any development of disease in the unaffected hemisphere (► Fig. 65.4).

65.13 Treatment Alternatives

There are no proven effective nonsurgical therapies for the prevention of stroke in patients with MMD. Endovascular therapy in the form of angioplasty, with or without stenting of the

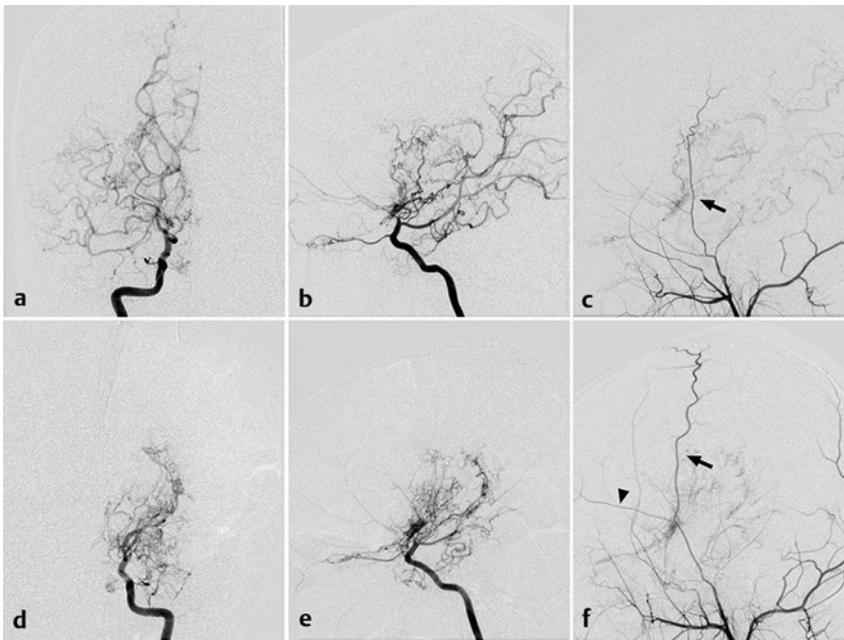

Fig. 65.3 Digital subtraction angiography of the patient described in ► Fig. 65.2. Anteroposterior (a) and lateral (b) projections of a right ICA injection demonstrating occlusion of the ICA distal to the posterior communicating artery and multiple small moyamoya collateral vessels. Lateral projection of the right external carotid artery (ECA) injection (c) demonstrating the parietal branch of the superficial temporal artery (*arrow*). Anteroposterior (d) and lateral (e) projections of a left ICA injection demonstrating occlusion of the ICA distal to the posterior communicating artery and multiple moyamoya collateral vessels. (f) Lateral projection of the left ECA injection demonstrating the frontal (*arrow-head*) and parietal (*arrow*) branches of the superficial temporal artery.

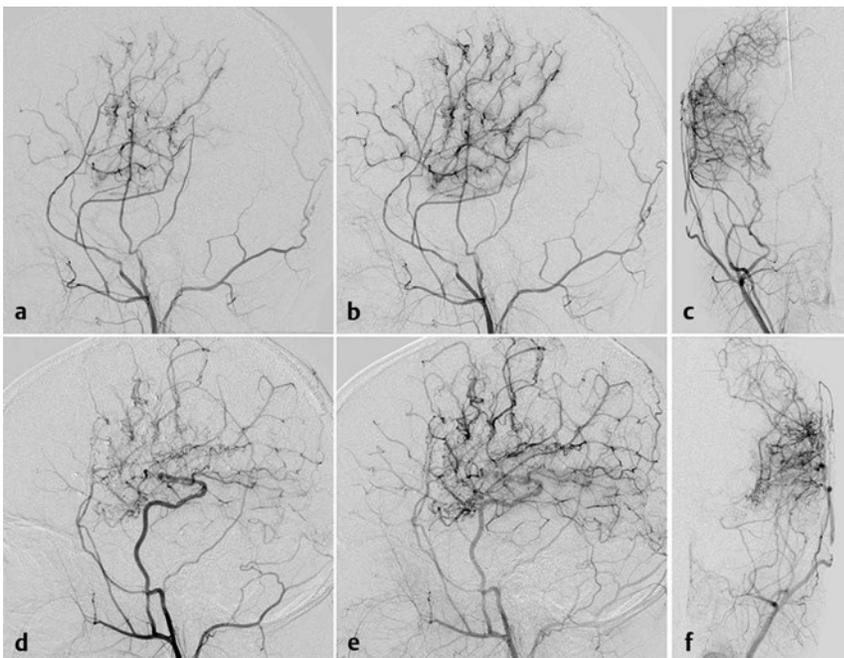

Fig. 65.4 Post-treatment angiogram of the patient described in ► Fig. 65.2 and ► Fig. 65.3. This angiogram was obtained 6 months after bilateral superficial temporal artery–middle cerebral artery (STA–MCA) bypasses for moyamoya disease. The patient had complete resolution of the transient ischemic attacks following surgery and remained neurologically intact. Early (a) and late (b) arterial-phase lateral images and anteroposterior image (c) of a right external carotid artery (ECA) injection demonstrating filling of most of the right MCA territory. Early (d) and late (e) arterial-phase lateral images and anteroposterior image (f) of a left ECA injection demonstrating filling of approximately two-thirds of the left MCA territory.

involved vasculature, has been ineffective. Khan et al reported a series of 5 patients with MMD treated with angioplasty and/or stenting in whom restenosis occurred within 13 months of treatment.³¹ All patients with a diagnosis of MMD are treated with 81 or 325 mg of aspirin daily, which may reduce the risk for thrombus formation or graft stenosis/occlusion. There is no direct evidence supporting the efficacy of this practice, but it is safe. To prevent dehydration from precipitating TIAs or strokes, patients are counseled to maintain adequate hydration at all times and are treated with intravenous fluids throughout any hospitalization.

65.14 Complications

Although cerebral revascularization procedures for MMD are generally safe, there is a risk for stroke or intracerebral hemorrhage in the perioperative period. In the Stanford series of 450 revascularization procedures in adult and pediatric patients with MMD, ischemic stroke occurred in 3% of patients (1.7% of hemispheres) during the perioperative period. Half of these strokes occurred in the treated hemisphere and half in the contralateral hemisphere. By 6 months, half of the patients had made a full neurologic recovery. Transient neurologic episodes

occurred in 3.3% of patients 3 to 7 days after surgery, all of whom recovered fully within 2 weeks. The etiology of these episodes is unclear because there was no MR imaging evidence of stroke; some authors believe they represent cerebral hyperperfusion.³² Intracerebral hemorrhage occurred in 2.6% of patients (1.8% of hemispheres) during the perioperative period. All hemorrhages occurred in previously ischemic territories that had been reperfused, not at the anastomosis sites. Fatal hemorrhage occurred in 0.75% of patients within 30 days of surgery.⁸ In a series reported by Scott et al of 143 pediatric patients with MMD or MMS who were treated with pial synangiosis, the perioperative stroke rate was 7.7% per patient and 4% per treated hemisphere.¹³ Preoperative neurologic instability (major stroke within 1 month before surgery or multiple strokes within 3 months before surgery) was found to be a risk factor for perioperative stroke. This series included 1 acute subdural hematoma and 3 chronic subdural hematomas. There were no perioperative intraparenchymal hemorrhages. In a systematic review of revascularization procedures for pediatric MMD, Fung et al identified 57 articles that documented 1,448 patients. They found the perioperative stroke rate to be 4.4% and the perioperative hemorrhage rate to be 1.7%.³³ Direct revascularization procedures appear to carry a lower risk for perioperative ischemia because of the achievement of immediate revascularization.²¹

65.15 Prognostic Factors

The most powerful predictor of MMD revascularization surgery outcome is the clinical status before treatment. Kim et al found infarction at presentation to be the most powerful predictor of outcome in their series of 410 consecutive cases of revascularization for MMD.³⁴ In the Stanford series of MMD revascularization procedures, Guzman et al also found that children who presented with stroke had an increased risk for surgical complications and that children who underwent indirect revascularization had a 2.5-fold increased risk for perioperative stroke in comparison with their direct-bypass counterparts.⁸

65.16 Outcomes

Outcomes after cerebral revascularization procedures for MMD and MMS are excellent overall. In the series of 410 pediatric MMD cases reported by Kim et al, 81% of patients had resolution of TIAs or seizures after revascularization and achieved a stable or normal neurologic status.³⁴ Perfusion MR imaging and SPECT studies demonstrated improved cerebral hemodynamics in 65% and 60% of patients, respectively. In the Stanford revascularization series, which included adult and pediatric patients with MMD, long-term follow-up showed significant overall improvement in functional status as measured by the modified Rankin Scale score. More than 90% of patients who presented with TIAs were free of TIAs at 1 year or more following surgery.⁸ In their systematic review of pediatric MMD revascularization procedures, Fung et al found that 87% of patients had a reduction or resolution of symptomatic cerebral ischemia at follow-up.³³

On delayed angiography, 99% of bypasses were patent in the Stanford series of bypass for MMD.⁸ Confirmation of

angiographic success is less easily measured after indirect revascularization procedures. In 18 hemispheres (adult and pediatric) treated with EDAS and multiple bur holes, the STA diameters and MMA diameters were both increased by a mean of 50%. A new angiographic blush associated with the STA and MMA was noted in 68% and 78% of hemispheres, respectively.³⁵ On delayed angiography in the series published by Scott et al, 65% of 195 hemispheres that had been revascularized via pial synangiosis demonstrated revascularization of more than two-thirds of the MCA territory. A further 25% showed revascularization of between one-third and two-thirds of the MCA territory.¹³ The long-term efficacy rates of revascularization with direct and indirect techniques in pediatric patients with MMD are comparable, with no other demonstrably superior techniques in the literature to date.²¹

Patients who continue to have TIAs or strokes following revascularization surgery may benefit from repeated revascularization. Pandey and Steinberg reported complete resolution of TIAs and no new strokes in 80% of patients who underwent repeated revascularization in a series of 16 patients (10 pediatric patients). One patient died, and no other patients worsened neurologically after repeated surgery.³⁶

65.17 Conclusion

MMD is a treatable cause of pediatric ischemic stroke. Surgical revascularization is the only effective treatment for preventing stroke in this patient population. Symptomatic patients and patients with imaging evidence of decreased cerebrovascular reserve should be offered surgical revascularization. Outcomes following revascularization are excellent, with low rates of new or recurrent stroke or TIA.

Pearls

- Revascularization surgery should be offered to all patients with MMD who have symptomatic cerebral ischemia or imaging evidence of reduced cerebrovascular reserve.
- Direct STA–MCA bypass provides immediate revascularization and thus appears to have a slightly lower risk for perioperative stroke than indirect revascularization.
- Direct STA–MCA bypass is not technically feasible in all children with MMD. Inadequate size of STA or recipient M4 branches is the most common reason why direct bypass cannot be performed.
- Indirect revascularization techniques also provide safe, effective revascularization of cerebral territory at risk for stroke in patients with MMD.

66 Intracerebral Aneurysms

Aaron J. Clark, Jason M. Davies, Kurtis Ian Auguste, and Michael T. Lawton

Pediatric intracerebral aneurysms are rare, having an overall incidence of 0.6%,¹ and are even rarer in infancy.² The annual incidence of new intracerebral aneurysms in children has not been reported. The annual incidence of hemorrhagic stroke from newly diagnosed intracerebral aneurysms in children is 0.18 per 100,000. Approximately 800 cases of pediatric intracerebral aneurysms have been reported in the literature to date, mostly in the form of case reports and series. However, because of the threat of rupture with potentially devastating neurologic sequelae, it is imperative that pediatric specialists make the appropriate diagnosis and initiate multidisciplinary treatment in a timely manner. Pediatric patients' extremely long life expectancy following treatment likewise demands that treatment durability be critically assessed.

The mantra in pediatric specialties is that "children are not little adults." The management of pediatric intracerebral aneurysms embodies this concept. Pediatric aneurysms differ from those in the adult population with respect to aneurysm presentation, location, size, morphology, and natural history. In fact, it has been proposed that pediatric and adult aneurysms are distinct pathologic entities. Whereas aneurysms in adults are more prevalent in women, those in children show a slight male predominance.³ Some have noted a bimodal age distribution in the pediatric age group. In modern series, subarachnoid hemorrhage is not the most common presentation.^{4,5} Saccular aneurysms are more likely to present with subarachnoid hemorrhage, whereas fusiform aneurysms are more likely to present with symptoms of mass effect.⁴ When subarachnoid hemorrhage is present, it generally manifests with a low grade on the Hunt and Hess Scale.^{6,7} The incidence of clinically significant vasospasm after rupture is also significantly lower.^{8,9} Nevertheless, cerebral infarction secondary to vasospasm does occur in children and should be recognized and treated expeditiously.^{7,10,11}

Aneurysms are most often located at the internal carotid bifurcation.^{7,8,12,13} Compared with those in adults, pediatric aneurysms are more commonly located in the posterior circulation and are more likely to be giant.^{3,5,6} Fusiform morphology is relatively more common in children.^{5,14} Infectious ("mycotic") aneurysms are generally located either distally in cortical vessels or close to the skull base and cavernous sinus, are usually fusiform, and may be multiple. Pediatric aneurysms demonstrate the capacity to arise *de novo* and to grow rapidly.^{3,15,16}

66.1 Diagnosis and Initial Management

The initial test in a child with suspected subarachnoid hemorrhage is noncontrast computed tomography of the head. Subarachnoid hemorrhage is the most common pattern of bleeding observed in children with ruptured intracerebral aneurysms. Intracerebral hematoma with or without subarachnoid hemorrhage is rare. In patients with a convincing history to suggest subarachnoid hemorrhage but without CT evidence of blood products, a lumbar puncture should be performed. Blood in the cerebrospinal fluid (CSF) or on a CT scan is further evaluated by

vascular imaging. Despite significant advances in CT angiography and magnetic resonance (MR) angiography, conventional four-vessel angiography remains the gold standard for defining the intracranial vascular anatomy. For patients with unruptured aneurysms, MR angiography may be the initial imaging modality. The choice of imaging modality is individualized on a case-by-case basis, with the goal of reducing radiation exposure while obtaining the necessary information to plan subsequent interventions.

Patients who present with a Glasgow Coma Scale score of 8 or less require intracranial pressure monitoring. External ventricular drains are preferred over intraparenchymal pressure monitors because they offer the possibility of CSF drainage to treat elevated intracranial pressure and hydrocephalus and the drainage of blood products in patients with intraventricular hemorrhage. External ventricular drainage is continued peri- and postoperatively. In general, the use of ventricular catheters is continued for the duration of the vasospasm risk period (days 3 through 17 after the bleed). There are cases of children who have reliably improving neurologic examinations with no imaging evidence of ventriculomegaly and a low Fisher grade in whom early removal of the external ventricular drain can be considered. Patients with significant intraventricular blood require ventricular drainage until the CSF is clear of blood products. Before removal of the external ventricular drain, the drain is clamped and the neurologic examination is followed closely. If the examination remains stable, a CT scan of the head is obtained after 24 hours of clamping. If the ventricular size is stable, the ventricular drain is removed. Children who fail this "clamp trial" require ventriculoperitoneal shunting.

66.2 Indications for Surgical Treatment

66.2.1 Subarachnoid Hemorrhage

In a large historical series from 1971, Patel and Richardson reported on 58 pediatric patients who presented with ruptured aneurysms, 21 of which were treated medically.⁹ Of these patients, 12 died and only 8 survived without neurologic deficits. Storrs et al demonstrated that children with previously untreated subarachnoid hemorrhage had a worse grade when they presented for treatment and subsequently had worse outcomes.¹² This was also noted by Sharma et al.⁷ Therefore, presentation with subarachnoid hemorrhage from a ruptured aneurysm is an absolute indication for treatment. Symptoms of subarachnoid hemorrhage range from the acute onset of a severe "thunderclap" headache, meningeal signs (photophobia, nuchal rigidity), and seizure to a comatose state. Children tend to have a greater capacity than adults to recover after rupture, and we generally maintain an aggressive treatment posture for pediatric patients with aneurysms, even those presenting with poor grades on the Hunt and Hess Scale (► Fig. 66.1a–d).

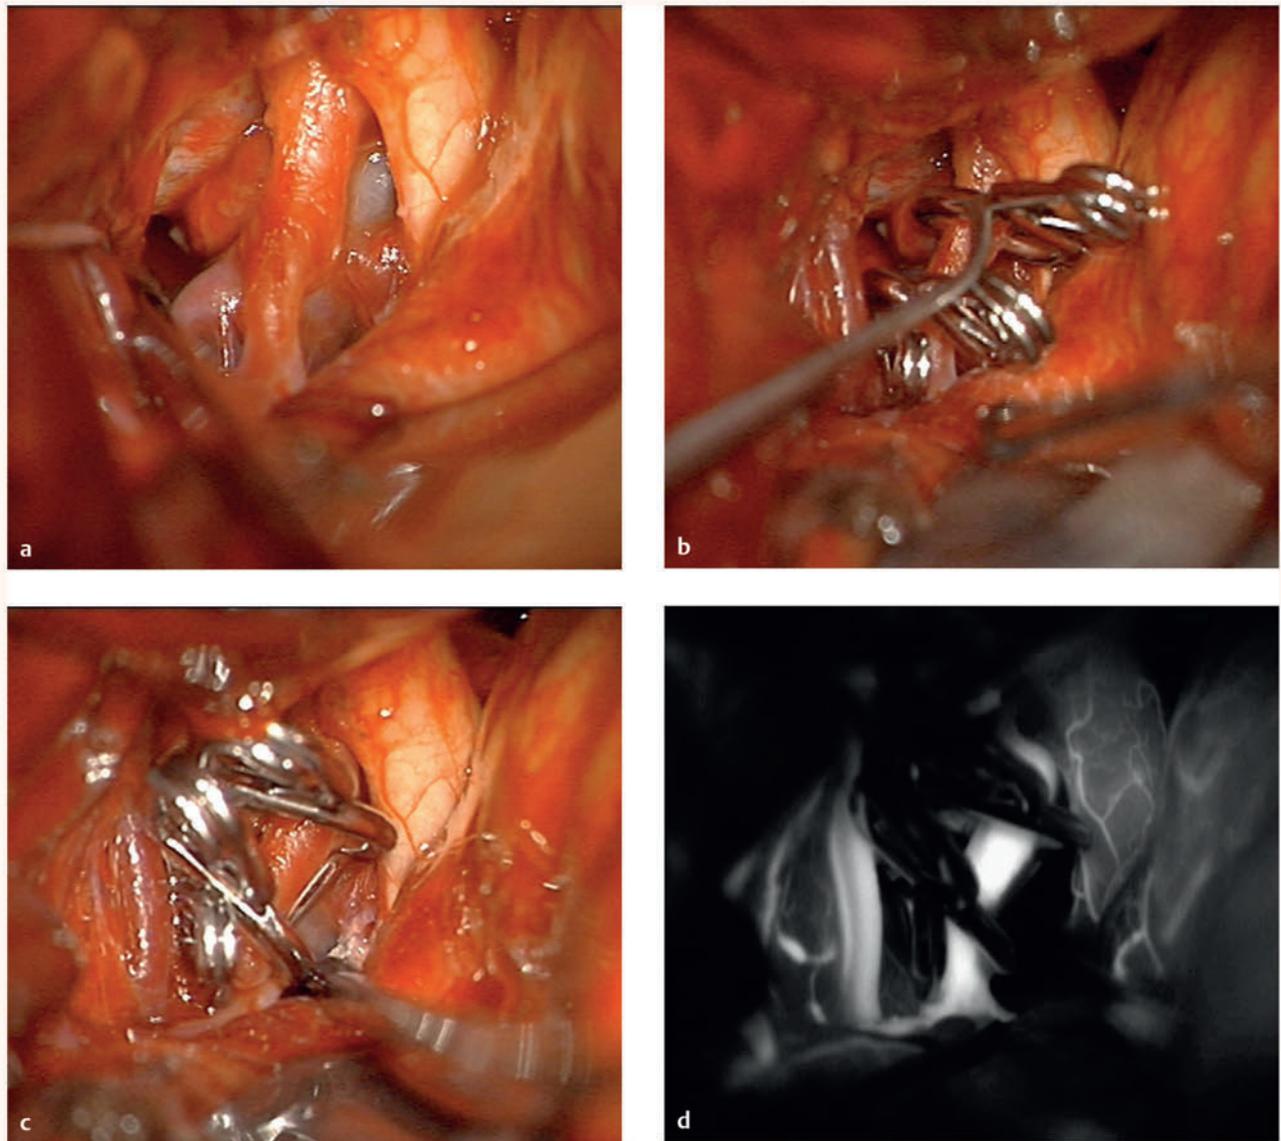

Fig. 66.1 (a) This 5-year-old girl presented with subarachnoid hemorrhage from a giant, thrombotic left internal carotid artery (ICA) aneurysm that was multilobulated. (b) Left pterional craniotomy exposed the aneurysm, which was clipped with two tandem right-angled fenestrated clips around the ICA. (c) A third clip occluded the posterior communicating artery as it exited the aneurysm. (d) Intraoperative indocyanine green dye demonstrated patency of the ICA and its branches.

66.2.2 Mass Effect

Pediatric patients who have an aneurysm with fusiform morphology, more than one aneurysm at presentation, and superimposed medical comorbidities are at increased risk for aneurysm enlargement or the development of new aneurysms.¹⁵ Symptoms attributable to mass effect range from headache, dizziness, and cranial nerve palsies to mono- or hemiparesis. Presentation with an enlarging aneurysm and progressive symptoms is an absolute indication for treatment.

66.2.3 Trauma

Traumatic aneurysms are associated with closed head injuries or penetrating head trauma. They are commonly associated

with skull base fractures. The injury induces a longitudinal vessel tear with the creation of a false lumen and subsequent dissection. Some are pseudoaneurysms, with injury to all vessel wall layers and hematoma encapsulation, having the imaging appearance of a true aneurysm. The supraclinoid internal carotid artery is the most common location for traumatic aneurysms. This anatomical location is most vulnerable because the proximal internal carotid artery is fixed at the dural entry by the distal dural ring and is more mobile distally where the carotid artery bifurcates to form the anterior cerebral and middle cerebral arteries. Particularly in a patient with a history of head trauma, a noncontrast CT scan demonstrating subarachnoid hemorrhage may be misinterpreted as traumatic subarachnoid hemorrhage. Because trauma can be associated with true or false aneurysms, subsequent vascular imaging is necessary. It

has been proposed that traumatic aneurysms may have a more favorable natural history because the artery involved is inherently normal and has the capacity to heal, whereas saccular or fusiform aneurysms arise from abnormal vessels.⁴ Nonetheless, traumatic dissecting aneurysms that present with subarachnoid hemorrhage are at risk for repeated hemorrhage, and treatment must be considered.

66.2.4 Infection

Infectious or mycotic aneurysms arise in the setting of endocarditis, septicemia, or human immunodeficiency virus infection.

Unruptured infectious aneurysms can be treated with appropriate intravenous antibiotics and frequent surveillance catheter angiography to document resolution or stabilization. However, documented growth or rupture of the aneurysm is an indication for definitive treatment (► Fig. 66.2a–k).

66.3 Surgical Treatment

Because of the complex and variable morphology of pediatric intracerebral aneurysms, a wide range of microsurgical techniques are required for their treatment. In an institutional series,

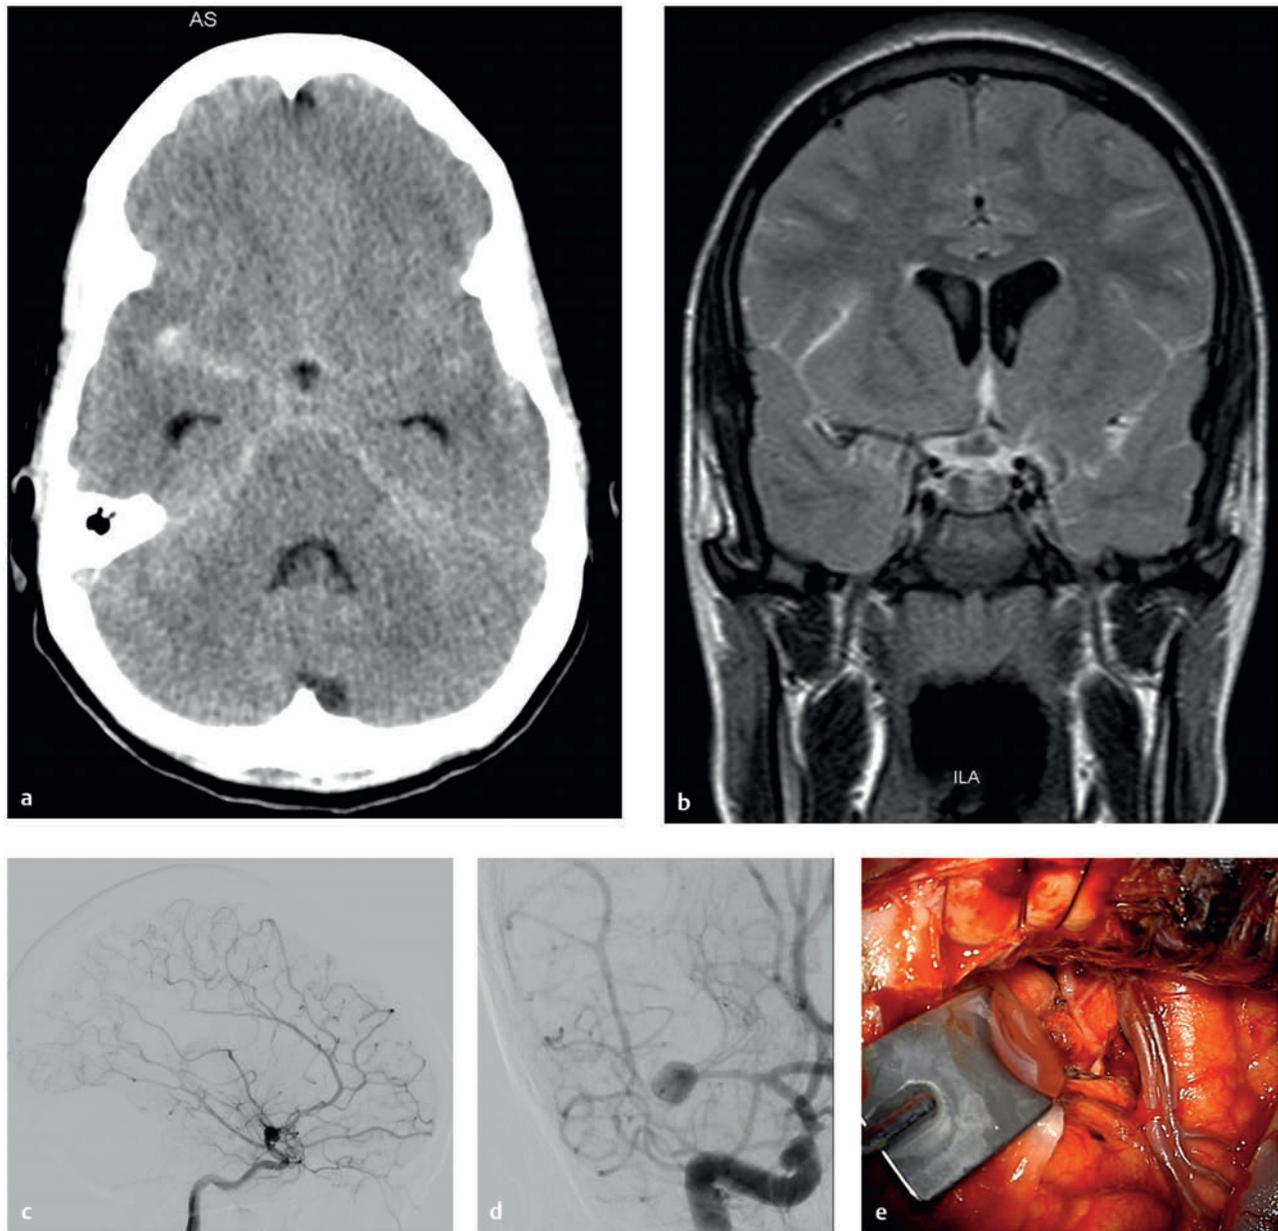

Fig. 66.2 This 17-year-old girl had a history of congenital heart disease and valve replacement surgery. (a) She presented with a subarachnoid hemorrhage as seen on an axial computed tomographic scan, and (b) a mycotic middle cerebral artery (MCA) aneurysm was seen on a magnetic resonance image. The aneurysm enlarged rapidly despite antibiotics, (c,d) as seen on catheter angiography, and she was transferred for surgical care. Note that the superior MCA trunk was occluded at this time. (e) The aneurysm was exposed through a right orbital-pterional craniotomy, (*continued*)

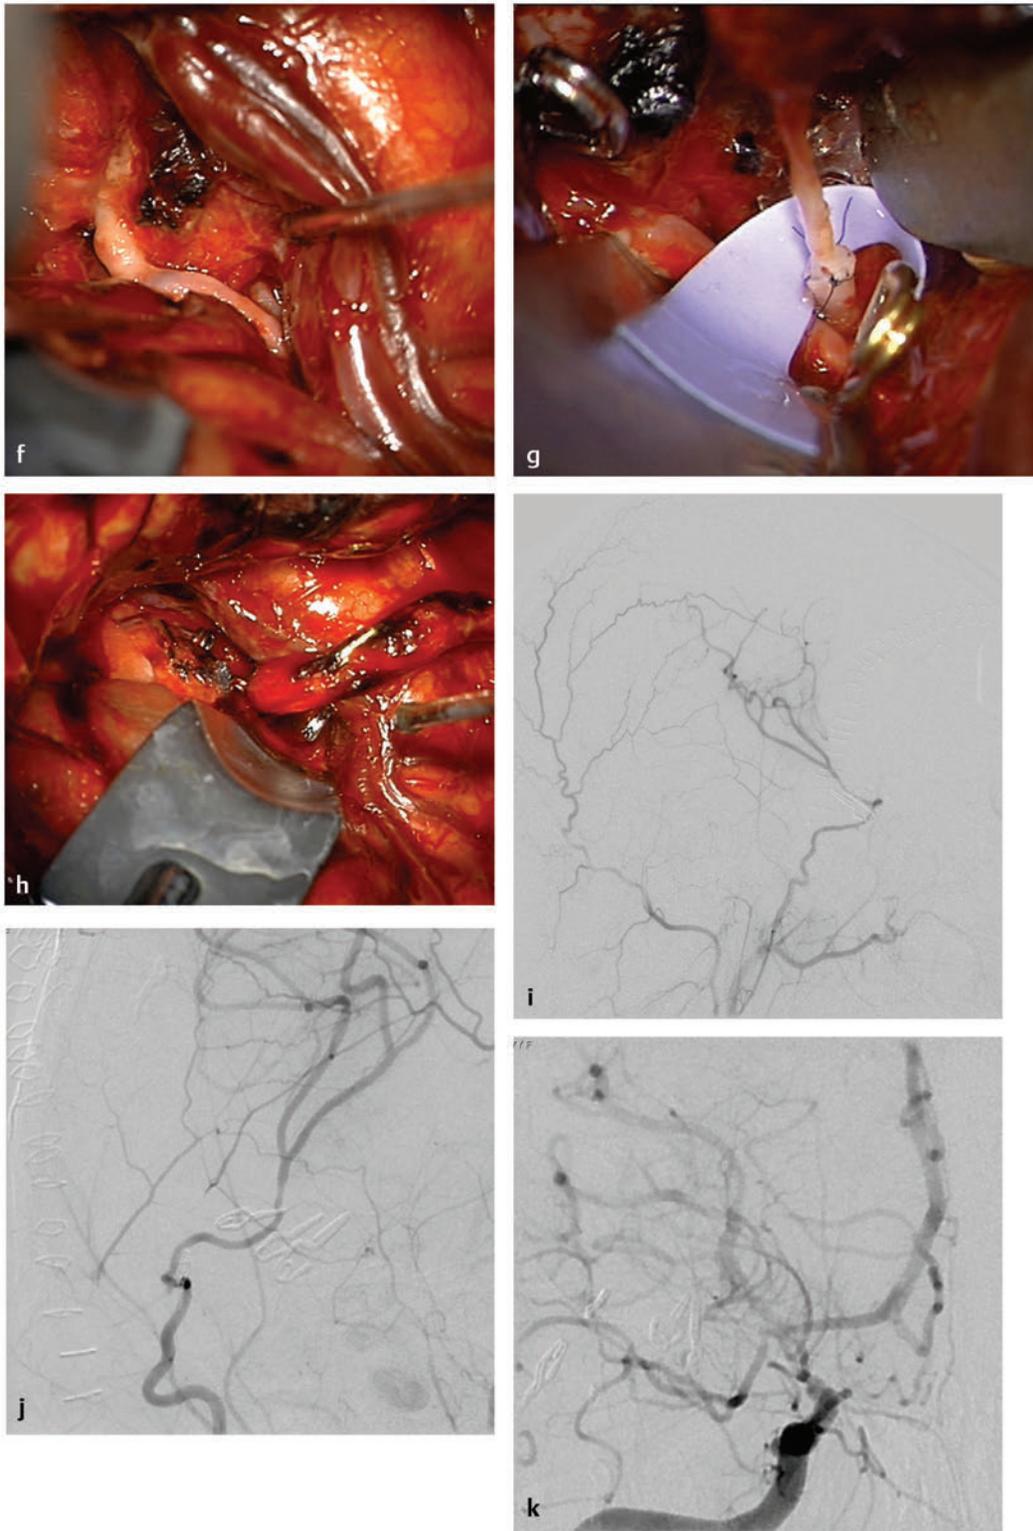

Fig. 66.2 (continued) and (f) inspection confirmed a mycotic aneurysm and a superior trunk occlusion. (g) The inferior trunk was revascularized with an end-to-end superficial temporal artery-to-MCA bypass, and (h) the aneurysm was trapped. (i,j) Post-operative angiography demonstrated the bypass filling the inferior trunk and angular arteries, and (k) the aneurysm was excluded completely with preservation of the lenticulostriate arteries.

we reported 13 patients treated initially with microsurgical techniques.⁵ Treatment techniques included direct surgical clipping, aneurysm trapping alone, trapping with extracranial-to-intracranial bypass, aneurysm excision with anastomosis, and proximal artery occlusion. A small number of patients in the initial microsurgical group required subsequent surgical or

endovascular treatment, underscoring the importance of interdisciplinary treatment planning and vigilant follow-up.

The variety of locations of pediatric intracerebral aneurysms mandates that the vascular neurosurgeon be comfortable with the different approaches to these anatomical locations. The standard pterional craniotomy gives access to many of the

anterior circulation aneurysms. The pterion, the lesser wing of the sphenoid, and the squamous portion of the temporal bone are removed with a high-speed drill in order to create a smooth, flat surface over the orbit connecting the anterior and middle cranial fossae. This allows an unobstructed view into the carotid cistern once the dura is opened and reflected. The orbitozygomatic craniotomy allows access to basilar tip aneurysms and can be used to gain greater exposure to giant and complex anterior circulation aneurysms. This approach includes the pterional craniotomy supplemented with removal of the orbital rim, orbital roof, lateral orbital wall, and zygomatic arch. Bifrontal craniotomy is used to approach pericallosal artery aneurysms. The medial border of the bone flap crosses the superior sagittal sinus, allowing exposure of the interhemispheric fissure once the dura is reflected medially. Care must be taken with bridging veins during this approach. Posterior inferior cerebellar artery aneurysms and aneurysms of the vertebral artery are approached through a far lateral craniotomy. This involves a C1 laminotomy, lateral occipital craniotomy, and condylectomy.

The treatment of choice for nongiant saccular aneurysms is direct surgical clipping. An aneurysm with a narrow neck and an uncomplicated anatomy can be clipped with a single appropriately sized and contoured clip. For an aneurysm with a broad neck or more complex anatomy, multiple clips oriented in intersecting, stacked, or overlapping configurations may be required. Giant saccular and fusiform aneurysms can also be treated by surgical clip reconstruction. In this technique, the arterial lumen is reconstructed with multiple surgical clips when a large size, wide neck, and/or abnormal branches prevent simpler clip applications. Complex clip reconstruction often requires proximal and distal temporary clips to soften the aneurysm, and it may be necessary to open the aneurysm to deflate it or remove thrombus intraluminally. Aneurysms not amenable to direct clipping may need to be trapped and bypassed ▶ Fig. 66.3a–m). A small subset of aneurysms can be excised with end-to-end anastomosis of the normal artery ends; however, this requires enough slack on either end for the ends to be brought together and sutured without tension.

Infectious aneurysms typically contain an infected arterial wall that must be completely excluded from the circulation. Therefore, aneurysm trapping is the preferred treatment, with bypass if needed. Traumatic aneurysms also have a weakened arterial wall that may not be able to hold a surgical clip, or the arterial wall may be involved circumferentially, in which case trapping and bypass is the preferred option.

Because of the large size and complex anatomy of some pediatric intracerebral aneurysms, surgical adjuncts such as cardiac standstill can be considered.^{11,17} Particularly useful for giant vertebrobasilar aneurysms, deep hypothermic circulatory arrest allows the giant aneurysm to be collapsed without bleeding, and dissection of the aneurysm can be performed without risk for rupture.¹⁸ However, this extreme intervention is becoming increasingly rare because bypass options, endovascular options, and combined therapies offer lower-risk alternatives.

Although not a definitive treatment and considered a treatment of last resort, aneurysm wrapping with muslin or other reinforcing material is also an option when other options fail.^{11,17}

66.4 Outcomes

Microsurgery is very successful at treating pediatric aneurysms definitively. In our series of aneurysms treated microsurgically, we reported a 93% rate of complete aneurysm obliteration.⁵ There were no recurrences at long-term follow-up. An 8% rate of formation of de novo aneurysms was noted. Others have reported similarly good results, with durable aneurysm cure after surgical therapy. Repeated hemorrhage is rare after treatment. In the Barrow Neurological Institute series of 48 children, reported by Kakarla et al, there was 1 event of repeated hemorrhage, which led to the only mortality.¹⁷ Lasjaunias et al reported 5 cases of repeated hemorrhage in a series of 59 children.¹⁴ There were 3 cases of repeated hemorrhage in 33 children with fusiform aneurysms, leading to 2 deaths and 1 poor neurologic outcome. In addition, there were 2 cases of repeated hemorrhage in 8 infectious aneurysms, both of which resulted in death.

In our series, 78% of patients treated microsurgically had good outcomes, defined as a Glasgow Outcome Scale scores of 4 or 5, indicating moderate disability or better. In a series of 13 pediatric intracerebral aneurysms treated with microsurgery, including 9 that were ruptured, Huang et al reported good outcomes in 95%.¹⁹ Similarly, in a large single-surgeon series of 52 patients with long-term follow-up, Aryan et al reported good to excellent neurologic outcomes in 81% of patients treated surgically.¹¹

In all large series of pediatric intracerebral aneurysms, aneurysm wrapping is a rare treatment modality. It appears that aneurysm size in patients who undergo wrapping remains stable; however, this is based on very low numbers reported.

66.5 Complications

66.5.1 Intraoperative Complications

Intraoperative aneurysm rupture is a reality of aneurysm surgery, regardless of the surgeon's skill and experience. Aryan et al reported 6 intraoperative aneurysm ruptures in their series of 52 operations (12%), which included 35 subarachnoid hemorrhages.¹¹ Kakarla et al reported a slightly lower rate of intraoperative ruptures: 2 in 54 operations (4%), including 16 subarachnoid hemorrhages.¹⁷ The immediate response to intraoperative rupture must be direct pressure with cottonoid, suction, temporary clipping, or trapping, followed by permanent clipping. Potential points of proximal control are identified preoperatively on angiography and are prepared early in the dissection. These may include the neck, which is prepared to gain access to the cervical internal carotid artery for proximal control of an ophthalmic artery aneurysm. Other points of control include the ophthalmic segment of the internal carotid artery for posterior communicating artery aneurysms, the M1 segment for middle cerebral artery aneurysms, bilateral A1 segments for anterior communicating artery aneurysms, the A2 segment for pericallosal artery aneurysms, the basilar trunk for basilar tip aneurysms, and the intradural vertebral artery for posterior inferior cerebellar artery aneurysms.

Perforating artery injury can be devastating. Liang et al reported 1 perforator injury in 4 pediatric aneurysms treated microsurgically.⁶ This perforator injury resulted in the only death

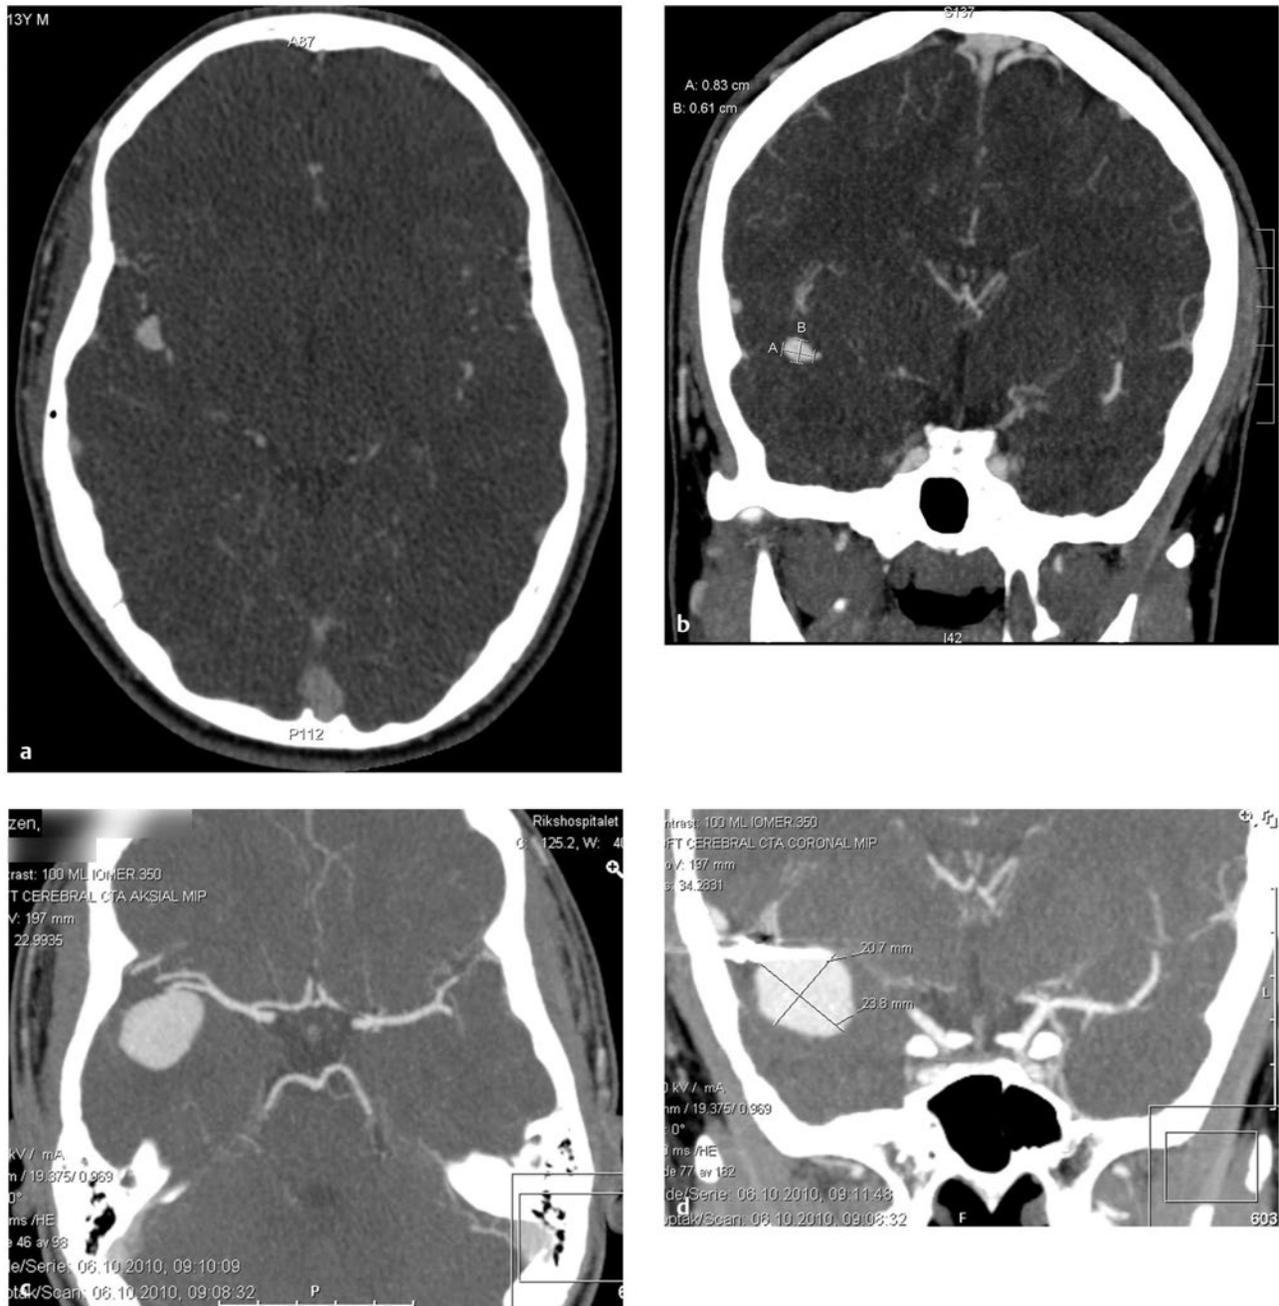

Fig. 66.3 This 15-year-old boy presented with a recurrent, giant distal middle cerebral artery (MCA) aneurysm. (a,b) He had presented 2 years earlier with a small MCA aneurysm arising from a bifurcation in the superior division of the MCA along the insular M2 segment. He underwent right pterional craniotomy and direct clipping in Norway, with no surgical complications. (c,d) Follow-up revealed aneurysm recurrence with marked enlargement, (e,f) as seen on computed tomographic angiography (*continued*)

in the series. Aryan et al¹¹ reported an 8% rate of intraoperative perforator injury, and Sharma et al⁷ reported a 2% rate. Perforators may be densely adherent to the aneurysm dome or may be hidden behind the aneurysm. After aneurysm clipping, we use indocyanine green video angiography to assess perforator and large branch patency. Aneurysms originating from parent arteries that have associated perforators must be meticulously inspected after permanent clipping to be certain that all

perforators have been excluded from the clips, which often requires aneurysm puncture and deflation to improve the view.

66.5.2 Postoperative Complications

In our series, there was 1 case of transient postoperative neurologic worsening and 1 case of permanent neurologic deficit.⁵ There were no mortalities. In the literature, postoperative

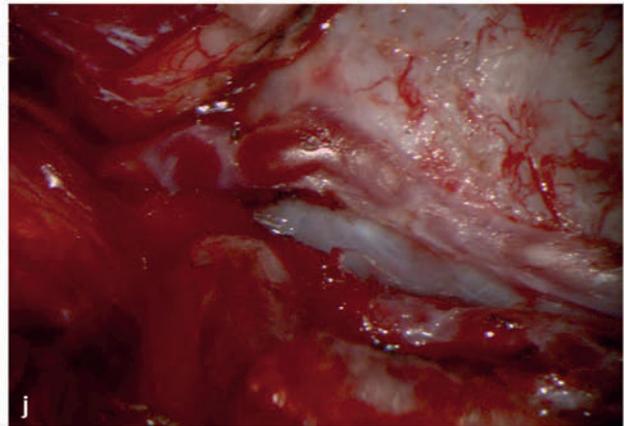

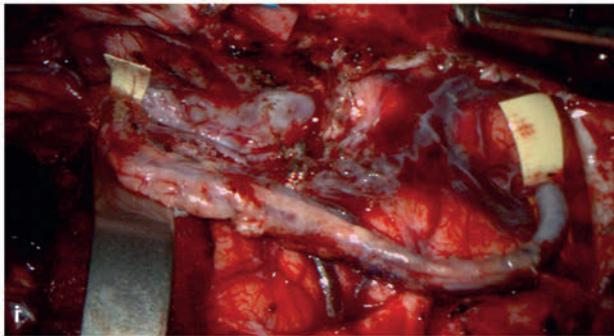

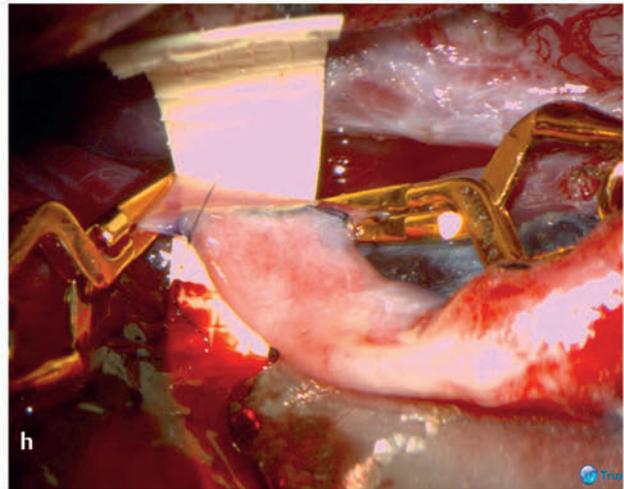

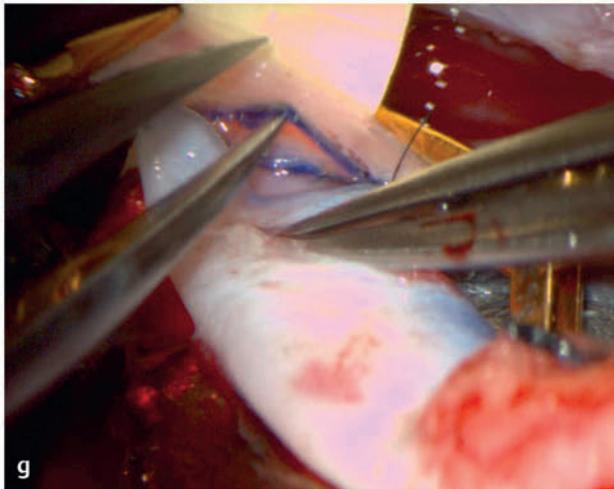

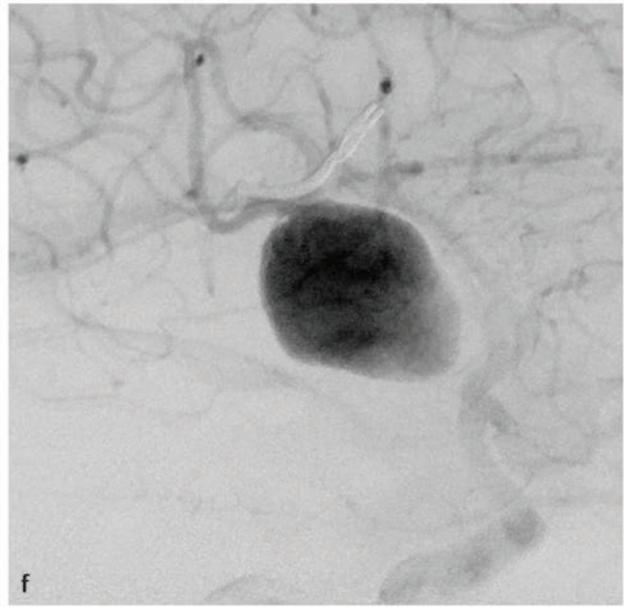

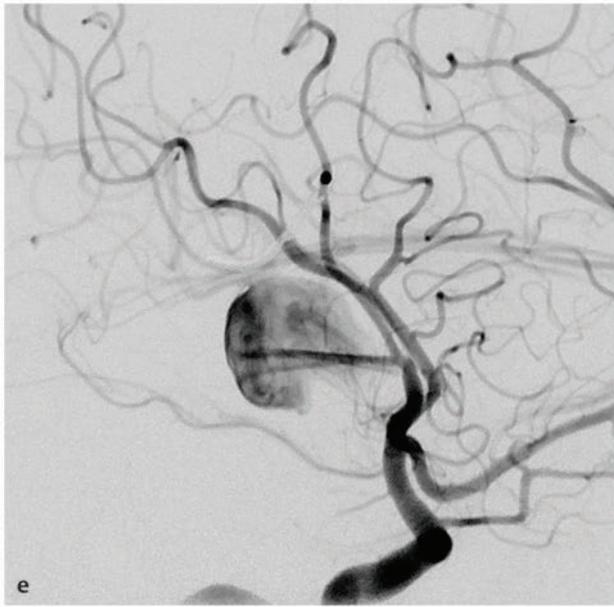

Fig. 66.3 (continued) and catheter angiography. (g,h) This aneurysm was treated with a bypass from the superior trunk of the MCA (i) to the efferent angular artery. (j) The aneurysm was then occluded proximally, but a branch of the inferior trunk adhered to the aneurysm wall. (continued)

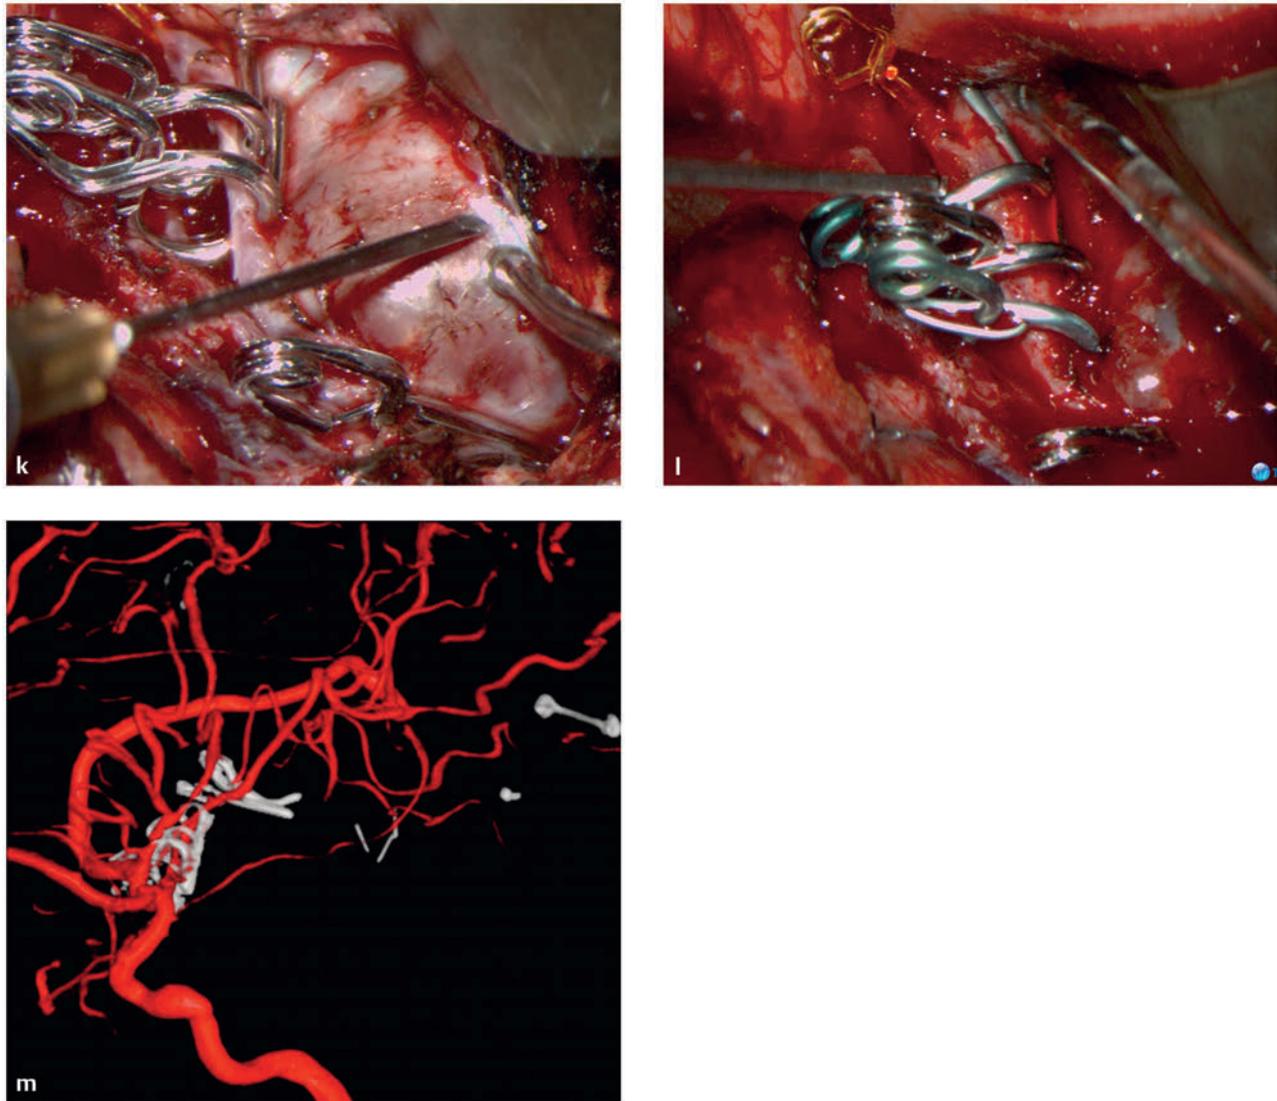

Fig. 66.3 (continued) Tandem fenestrated clips were used to reconstruct this adherent branch, but (k) suction decompression and (l) repositioning of the clips were required. (m) Postoperative angiography with three-dimensional reconstruction confirmed patency of all trunks and branches.

mortality after the surgical treatment of pediatric intracerebral aneurysms is also rare, ranging from 2 to 5%,^{3,7,11,17,19,20} as is postoperative aneurysmal rebleeding. Kakarla et al¹⁷ reported a 2% rate, and Meyer et al³ reported a 4% rate. Aryan et al¹¹ reported a 6% rate of postoperative stroke, an 8% rate of new hemiparesis, and a 6% rate of new cranial nerve deficits. There was a 4% rate of wound infection. Kakarla et al reported a 4% rate of stroke and a 6% rate of new postoperative neurologic deficits, including 2 new cranial nerve deficits.¹⁷ In the immediate postoperative period, they reported 1 epidural hematoma and 1 cerebellar hematoma, both of which required surgical evacuation. Occlusion occurred in 2 of 13 bypasses in the perioperative period. Sharma et al⁷ reported a 4% rate of postoperative stroke.

Although not a surgical complication, hydrocephalus develops in many patients with subarachnoid hemorrhage, and CSF diversion procedures are required. Careful attention must be paid postoperatively to signs and symptoms of hydrocephalus. It is generally thought that chronic hydrocephalus after subar-

achnoid hemorrhage results from the fibrosis of arachnoid granulations in response to the presence of blood products and subsequently impaired CSF resorption. As this is not an obstructive problem, we treat hydrocephalus related to subarachnoid hemorrhage with ventriculoperitoneal shunting, not endoscopic third ventriculostomy. Infectious meningitis is also a potential complication, related to either the surgical procedure or external ventricular drainage, and it must be detected and treated.

Although not a postoperative complication, delayed aneurysm recurrence is a concern in pediatric patients because of the dysplastic nature of some of these aneurysms, and also because of the long life expectancy of the patients. Postoperative catheter angiography is mandatory after treatment to confirm complete aneurysm occlusion. Furthermore, follow-up MR angiography is recommended annually for the first 5 years after treatment. The frequency of MR angiography can then be decreased to once every 5 years if no residual or new aneurysm is detected. For pediatric patients with multiple aneurysms,

continued angiographic surveillance throughout life is warranted to identify new aneurysms that may develop later in adulthood. We aggressively treat unruptured aneurysms that are identified in patients with previous subarachnoid hemorrhage, in accordance with the International Study of Unruptured Intracranial Aneurysms (ISUIA) recommendations. Furthermore, we aggressively treat de novo aneurysms because they are likely to be less stable and carry a higher risk for rupture than small, stable aneurysms that are incidentally diagnosed.

As mentioned above, angiographic vasospasm after intracerebral aneurysm is less common in children than in adults. Clinically significant vasospasm requiring therapy is even rarer. In a child with an acute neurologic change and suspected vasospasm, an emergent CT scan of the head should be obtained to rule out a surgical lesion such as an epidural hematoma. In the absence of this, “triple H” therapy should be immediately instituted: hydration with intravenous normal saline, hemodilution, and hypertension with vasopressors such as phenylephrine if needed. Vascular imaging should be considered. Our preference is catheter angiography because it provides the best resolution of the blood vessels and allows the opportunity to treat areas of stenosis with intra-arterial verapamil or angioplasty. At our institution, patients with subarachnoid hemorrhage and poor neurologic examinations are followed with daily transcranial Doppler studies. Elevated velocities prompt catheter angiography.

66.6 Treatment Alternatives

66.6.1 Observation

In a series of 59 pediatric patients with aneurysms, 8 aneurysms were observed to undergo spontaneous thrombosis and did not require further treatment.¹⁴ Liang et al demonstrated 2 cases of spontaneous thrombosis in a total of 24 patients.⁶ The primary reason for observation was the high risk for neurologic decline expected after treatment, although the specific risks were not defined. Unfortunately, the literature does not offer ways to predict which patients will do well with observation. In our institutional series, 18 patients with multiple areas of long-segment dysplasia that were unruptured were managed conservatively with observation.⁴ Interestingly, there were no events of bleeding during the observation period. Two aneurysms demonstrated subtle enlargement. One required endovascular coiling and one required endovascular balloon occlusion of the parent artery. Additionally, one demonstrated significant enlargement and underwent stent coiling. Therefore, because of the high risk for aneurysm enlargement and/or rupture, we strongly recommend the direct treatment of pediatric aneurysms. We do not advise observation for pediatric patients who have ruptured aneurysms or who have large or giant aneurysms with symptomatic mass effect. Small aneurysms less than 7 mm in diameter can be observed with serial imaging, but enlarging aneurysms should not be observed, even when they are less than 7 mm in diameter. Patients with long-segment dysplasia that is unruptured may be observed because this finding may not represent true aneurysm pathology, and it is associated with a benign clinical course in our experience. Children

who have other conditions associated with intracranial aneurysms, such as microcephalic osteodysplastic primordial dwarfism (MOPD) type 2, should be followed vigilantly for life.²¹

66.6.2 Endovascular Treatment

In our institutional series of 77 pediatric patients (defined as age less than 19 years) with intracerebral aneurysms, 19 underwent endovascular coiling as the primary treatment modality.⁴ There was one arterial injury related to the procedure, with subsequent cerebral infarction and monoparesis. There was one intraprocedural aneurysm rupture, which was treated endovascularly without sequelae. Three residual aneurysm remnants required treatment. One was treated with repeated coiling, one was treated with stent-assisted coiling, and one was taken to the operating room for aneurysm trapping and extracranial–intracranial bypass. There was one death due to rupture of a de novo aneurysm 20 months after primary treatment.

For some extensive fusiform aneurysms and very large saccular aneurysms deemed not amenable to either surgical clipping or endovascular coiling, parent artery occlusion can be considered. It is critical to first demonstrate adequate collateral circulation angiographically and, when possible, with awake balloon test occlusion. Hetts et al reported 11 such patients from our institutional series.⁴ All complications were transient: one hemiparesis, one monocular vision loss, and one sixth cranial nerve palsy. Three patients developed de novo aneurysms, two of which required surgical trapping and bypass. The third was stable with observation.

There is currently no consensus to guide the decision whether to treat patients microsurgically or endovascularly. Some argue that patients with aneurysms located at the basilar tip should be preferentially referred for endovascular coiling.¹⁰ Lasjaunias et al reported a series of 17 patients treated for fusiform aneurysms, of which 14 were treated endovascularly, suggesting their support of endovascular techniques for this type of morphology.¹⁴ Eleven patients underwent parent artery occlusion, two underwent proximal occlusion, and one underwent coiling.

We compared primary endovascular treatment and primary microsurgical treatment with respect to treatment durability.⁵ In comparison with our microsurgical results, we reported a 79% complete obliteration rate with endovascular treatment, as well as a 19% recurrence rate and a 19% de novo aneurysm formation rate (► Fig. 66.4a–i).⁵ Endovascular therapy offers good treatment options in selected aneurysms with favorable anatomy. Patient and parent preferences must be considered in the selection of a treatment modality, with a critical eye on efficacy and long-term durability. In general, endovascular therapy has greater parental appeal and slightly lower associated risks, but surgery has greater efficacy, durability, and protection against rebleeding.

66.7 Prognostic Factors

The small numbers included in currently available series limit our ability to identify prognosticators definitively. In patients

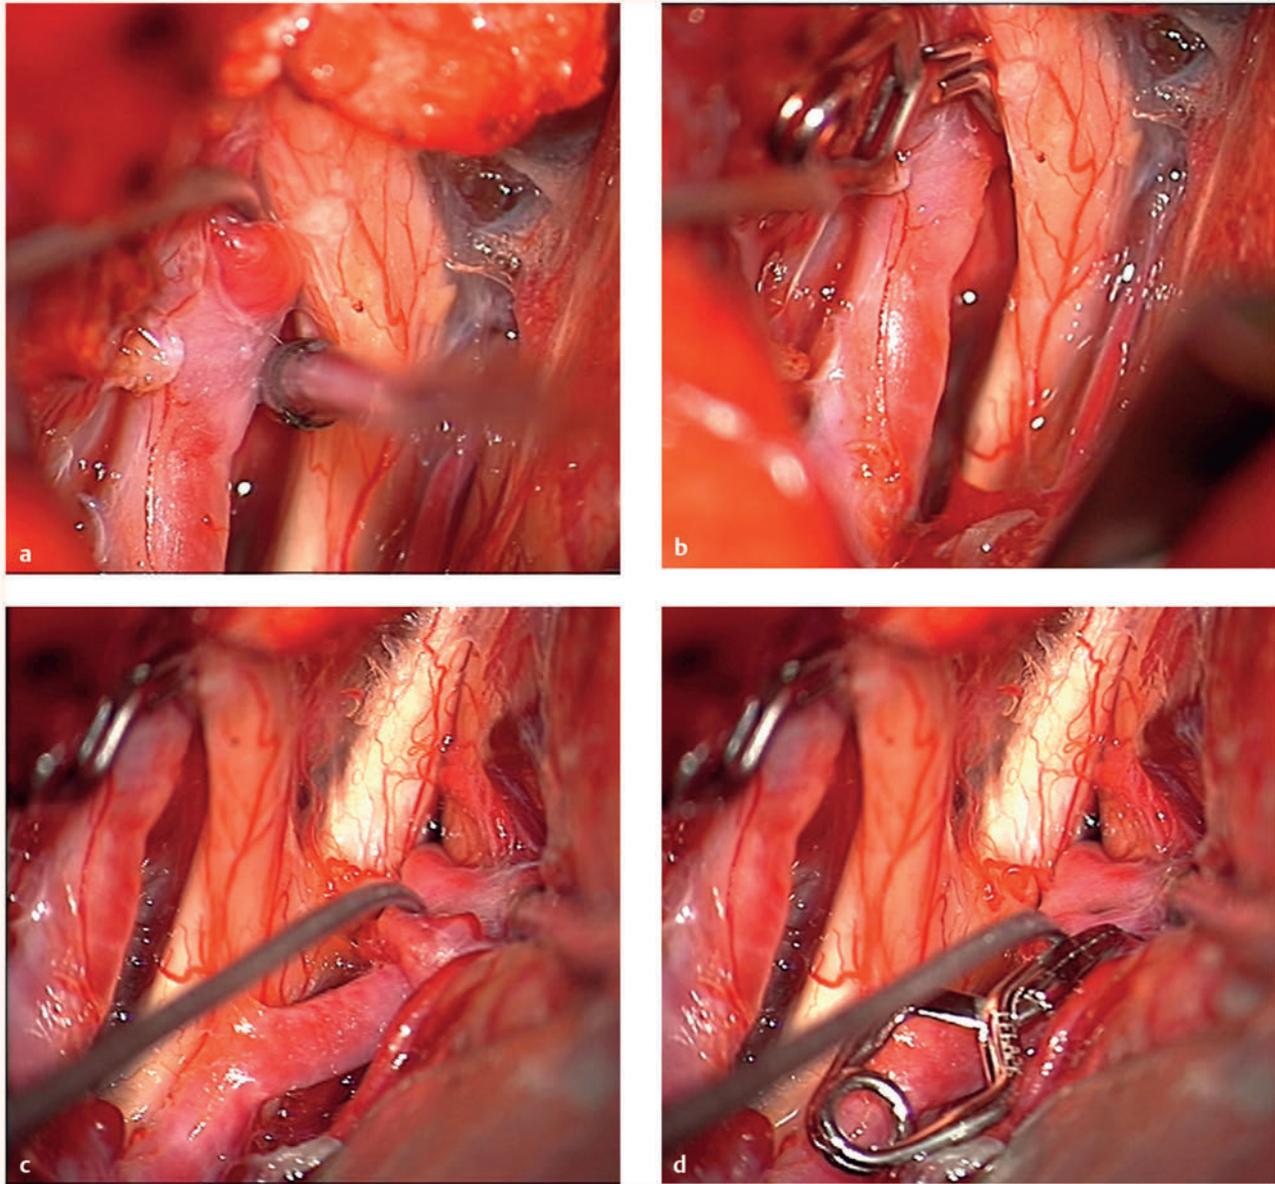

Fig. 66.4 This 14-year-old girl with sickle cell disease had a subarachnoid hemorrhage from a left superior cerebellar artery aneurysm and was treated with endovascular coiling. Surveillance angiography demonstrated enlargement of other aneurysms and de novo aneurysms. She underwent left pterional craniotomy for clipping of these multiple aneurysms. (a) The ophthalmic artery aneurysm was exposed after anterior clinoidectomy and (b) clipped with a side-angled clip. (c) Her small anterior communicating artery aneurysm (d) was clipped (*continued*)

who present with subarachnoid hemorrhage, the preoperative clinical grade appears to correlate with outcome. Storrs et al reported that patients who presented with a worse grade after subarachnoid hemorrhage had worse outcomes after surgery.¹² Likewise, Sharma et al noted that 90% of the patients who pre-

sented with a Hunt and Hess grade of 1 through 3 had good outcomes, and nearly 70% of those who presented with a grade of 4 or 5 had poor outcomes.⁷ Proust et al reported excellent outcomes in 85% of patients presenting with Hunt and Hess grade 1 through 3 subarachnoid hemorrhages.⁸

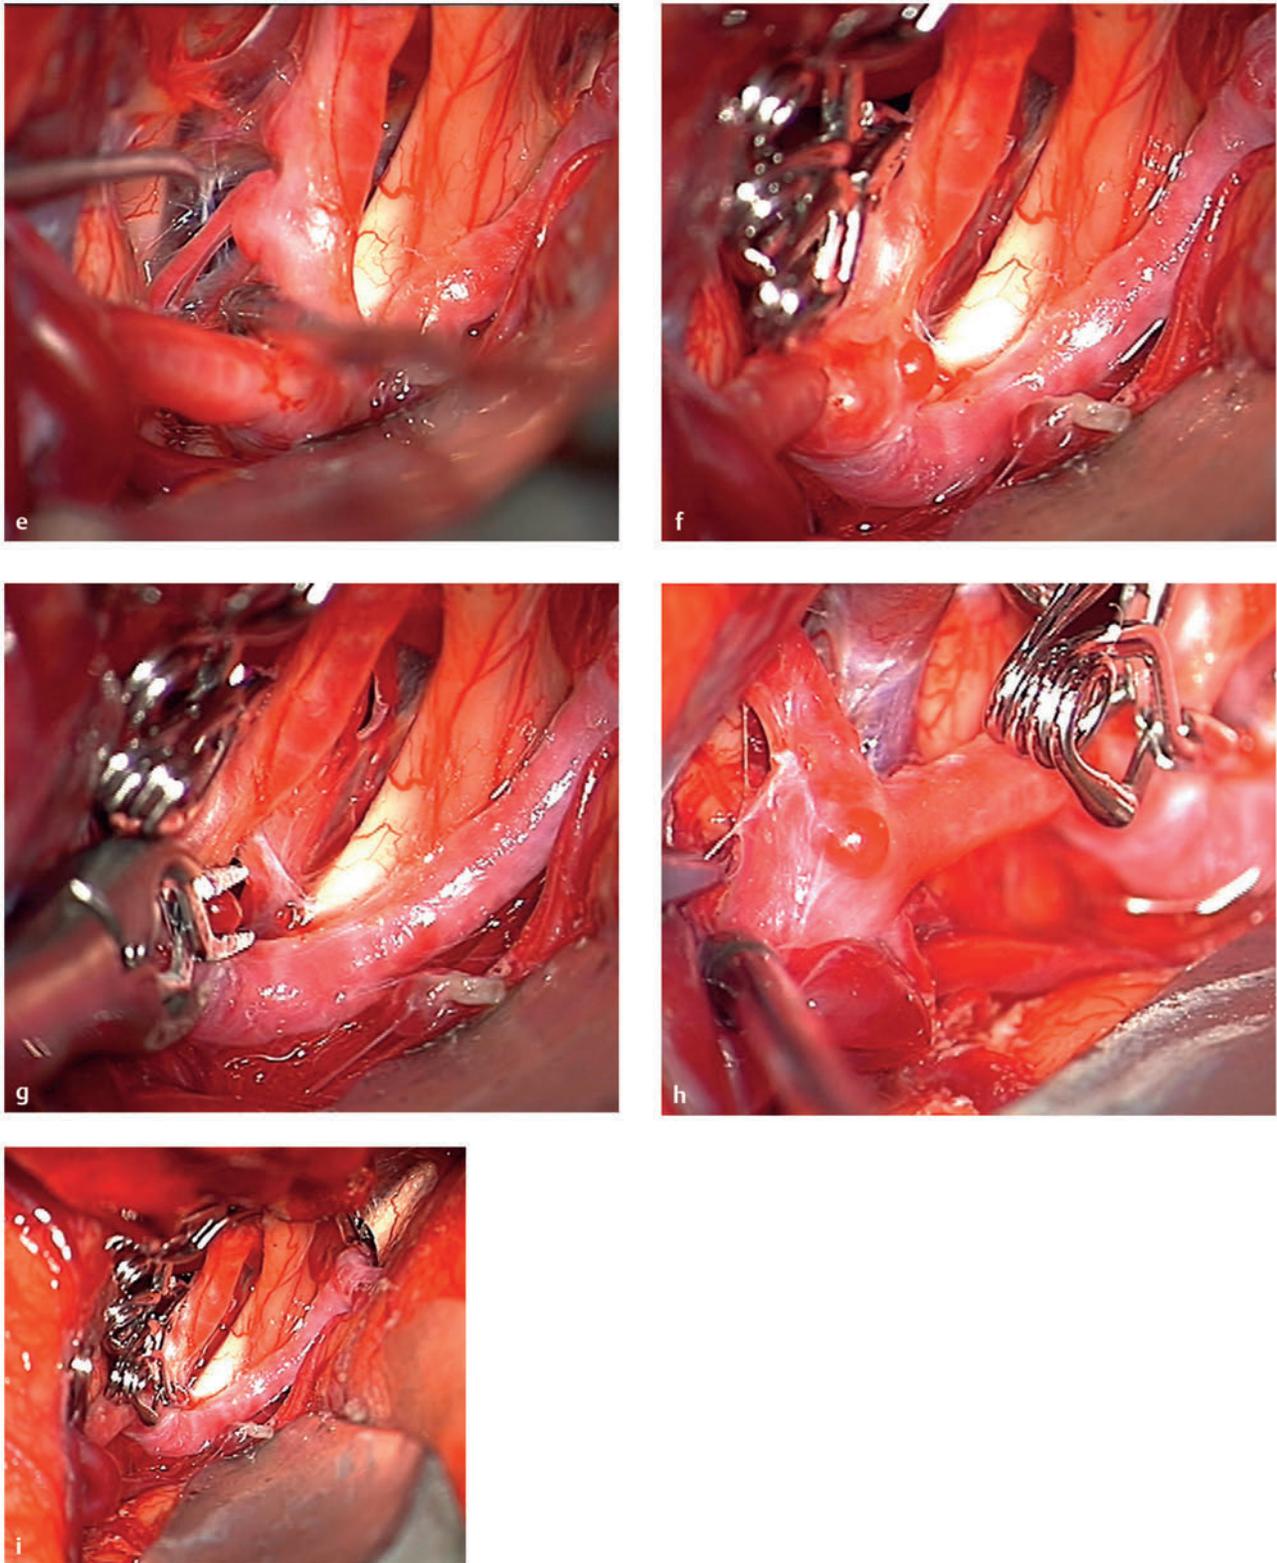

Fig. 66.4 (continued) (e) as were posterior communicating, anterior choroidal, (f,g) internal carotid artery bifurcation, and(h) middle cerebral artery aneurysms. All aneurysms were small and very thin-walled. (i) One craniotomy accessed all six aneurysms.

Pearls

- When a pediatric patient presents with an aneurysm, the dynamics of selecting a treatment modality are considerably different from those for an adult with a similar lesion.
- Although concerns for safety and efficacy remain a priority, the issue of durability of treatment takes on new meaning for a child with five to seven decades of life remaining.
- In our experience, the complication rates, morbidity, and mortality of operative versus endovascular treatment have been comparable. With respect to efficacy, both modalities have also been comparable.
- In regard to durability, however, the increased recurrence rate demonstrated in the endovascular treatment population, even after a modest follow-up period, warrants serious consideration. Furthermore, the incidence of delayed complications from de novo aneurysm formation was considerably higher in the patients who underwent endovascular treatment. These results of endovascular treatment inevitably led to additional therapy, often in the form of definitive microsurgical treatment.
- Although the intrinsic appeal of endovascular therapy to parents must be recognized and respected, parental bias must be tempered by a serious consideration of therapeutic durability, the potential for delayed complications, and the need for additional treatment later in life.
- By these criteria, microsurgical intervention may be superior to endovascular treatment because the long life expectancy of pediatric patients requires us to redefine our concept of treatment permanence.
- At present, with little evidence in children, the treatment of symptomatic vasospasm follows the adult guidelines of “triple H” therapy with hydration, hemodilution, and hypertension.

67 Pediatric Arteriovenous Malformations

Edward R. Smith

Vascular malformations of the central nervous system are a heterogeneous group of lesions that occur in both the brain and the spinal cord. Like those in other anatomical sites, vascular anomalies of the central nervous system can be classified according to rheologic characteristics (fast-flow and slow-flow) and by channel composition (i.e., arteriovenous malformation [AVM], cavernous malformation [CM], and venous malformation [VM]) and may occur either independently or in association with syndromic conditions. AVM is arguably the most important vascular anomaly in the nervous system in children; it is relatively common and usually requires treatment given the risk for hemorrhage.

67.1 Pathophysiology

AVMs consist of direct arterial-to-venous connections without intervening capillaries; they occur in the cerebral hemispheres, brainstem, and spinal cord. Functional neural tissue does not reside within the lesion.¹ Anomalies range from simple arteriovenous fistulas to complex tangled channels connecting enlarged feeding arteries to draining veins.

AVMs may increase in size over time or may demonstrate changes in the caliber of component vessels, which may portend a risk for hemorrhage. These changes may occur from “mechanical” dilation as the result of increased flow through poorly differentiated vessels and the recruitment of collateral arterial feeders. Ischemia and surrounding microhemorrhages with resultant gliosis may promote the enlargement of an AVM by destruction of the surrounding parenchyma. Expansion of an AVM may also result from the growth of new blood vessels (i.e., angiogenesis, which is a complex process regulated by a wide range of proteins, including metalloproteinases and related growth factors, such as vascular endothelial growth factor).²⁻⁸ Enlargement of an AVM seems to alter the adjacent brain. Functional magnetic resonance (MR) imaging data have suggested that the presence of an AVM in an eloquent area of the brain may be associated with “migration” of the function to adjoining cortex or to the homologue on the contralateral hemisphere.^{9,10} This migration or displacement of functional neuronal tissue has important implications for surgical planning.

67.2 Epidemiology

AVM is the most common symptomatic high-flow intracranial vascular abnormality in adults and children.¹¹ In a large autopsy series, the overall frequency of detection for AVMs was 1.4% (46 of 3,200 cases of brain tumor).¹² In another report, the annual incidence of symptomatic AVMs was 1.1 per 100,000.¹³ The pediatric age group accounts for 12 to 18% of all AVMs from major centers, and the overall prevalence in children is about 0.02%.¹⁴⁻¹⁷ Most AVMs present in adulthood, with a mean age of patients at presentation of approximately 30 to 40 years. About 20% of all symptomatic AVMs present before 15 years of age.¹⁸ There is no sex predilection for pediatric AVMs. A number

of AVMs are associated with underlying genetic conditions. The *RASA1* mutation, resulting in familial AVMs and/or cutaneous capillary malformations, has been associated with symptomatic cerebral AVMs in a small number of families.¹⁹ Hereditary hemorrhagic telangiectasia is a genetic condition that predisposes affected individuals to AVMs. Thirty-five percent of pediatric cases were associated with hereditary hemorrhagic telangiectasia. Twenty-three percent of patients had multiple AVMs, with a mean age at presentation of 35 years¹³

67.3 Presentation

The neurologic signs and symptoms of central nervous system vascular anomalies correlate with the anatomical site of involvement and the age at presentation. The lesions can be deep in the parenchyma, superficial, or located in the dural and arachnoid coverings. In general, AVMs that are symptomatic at or soon after birth are extremely fast-flow lesions and often are associated with high-output cardiac failure. The more common pial AVMs usually present with hemorrhage later in childhood or adulthood. The likelihood and severity of symptoms and the probability of hemorrhage caused by the vascular anomaly depend on multiple factors, including type of malformation, size, location, and hemodynamic and angioarchitectural characteristics.

Hemorrhage and seizure are the most common presenting symptoms of pediatric AVM, but the findings may also include headache, focal neurologic deficits, and cognitive decline.²⁰⁻²³ A substantially large number may be asymptomatic.

Children with AVM are more likely than adults to present with intracranial hemorrhage: 80 to 85% in some pediatric series.^{15,24} For children known to have an AVM, the annual risk for hemorrhage has been estimated at 2 to 4%.^{25,26} Hemorrhagic events from an AVM in childhood have been associated with a 25% mortality rate.²⁷ In contrast to earlier reports suggesting that smaller AVMs may be associated with a higher risk for bleeding, more recent data have shown that size is not a major determinant in the risk for hemorrhage.^{28,29}

The hemorrhage can produce seizures, headache, or focal neurologic deficits. The bleeding associated with an AVM is most often an intraparenchymal hemorrhage, although subarachnoid hemorrhage and intraventricular hemorrhage are also common. Bleeding can occur in any one location or in all three sites together.³⁰⁻³² A nontraumatic intraparenchymal hemorrhage in a child should raise concerns for the presence of an AVM or tumor. Rates of rebleeding have been reported to be approximately 6% within the first 6 months.

Independently of hemorrhage, AVMs can produce deficits from mass effect or from cerebral ischemia that is due to the diversion of blood to the AVM from the normal cerebral circulation (“steal”). The presentation of symptoms in AVM is generally acute if related to hemorrhage or seizure (often occurring within minutes to hours) but is chronic (over months) if related to a steal phenomenon or headache.

67.4 Physical Signs

Systolic bruits over the eye or through the head and or fontanelles are suggestive of an AVM; focal neurologic signs help localize the lesion. A bruit is found in 15 to 40% of patients with AVM. It is especially common if branches of the external carotid arteries are involved and best heard over the ipsilateral eye or mastoid region. Large, pulsatile vessels may be present in the scalp, face, and neck, and vascular anomalies can be found in retina. Major arteriovenous shunting may also be associated with tachycardia, cardiomegaly, and even cardiac overload, especially in infants and children and particularly when the vein of Galen is involved. Other than potential neurologic deficits, the typical patient will not have any obvious findings on general physical examination to suggest an underlying AVM.

67.5 Imaging

The comprehensive evaluation of a patient with an AVM includes a detailed history, neurologic and physical examination, and radiographic studies to delineate the anatomy of the lesion.³³ The vast majority of patients present with the new onset of a neurologic deficit, such as an unusually severe headache (“worst headache of my life”) or seizure due to acute hemorrhage. These patients should be screened with computed tomography (CT) (► Fig. 67.1, ► Fig. 67.2). CT is a reliable indicator of recent intracranial hemorrhage, may permit localization of the source of bleeding, and facilitates the early diagnosis of

AVM. Because of its speed, availability, and ease of use, CT angiography has increasingly been employed as an initial study upon presentation to the emergency department.³⁴ CT angiography better delineates AVM, particularly in the setting of an acute hemorrhage. In addition, the index of suspicion for an AVM is high whenever an intraparenchymal hemorrhage is found in a child or young adult without an antecedent history of trauma.³⁵ Repeated imaging in 4 to 6 weeks is indicated to evaluate the hemorrhagic cavity after the clot has cleared.³⁶

Infratentorial AVM typically appears as a heterogeneous area of mixed density with serpiginous areas of enhancement after the infusion of contrast material. Cerebral atrophy may sometimes be seen on the affected side. A large malformation or an intracerebral hematoma may distort the normal intracranial anatomy. A hematoma from AVM can be situated in the cortex or adjacent white matter, so that it usually can be distinguished from a hypertensive hematoma, which is often deeply placed. Intraventricular extension of the hematoma is common.

MR imaging is also useful in the diagnosis and delineation of the anatomy of AVM (► Fig. 67.1). MR imaging better localizes the parenchymal structures relative to the AVM, even if there is a strong suspicion of AVM based on the CT or CT angiographic findings and angiography is planned. The typical MR imaging appearance is that of a latticework of signal-void spaces highly contrasted against the surrounding cerebral tissue on both T1- and T2-weighted sequences. These are intermixed with regions

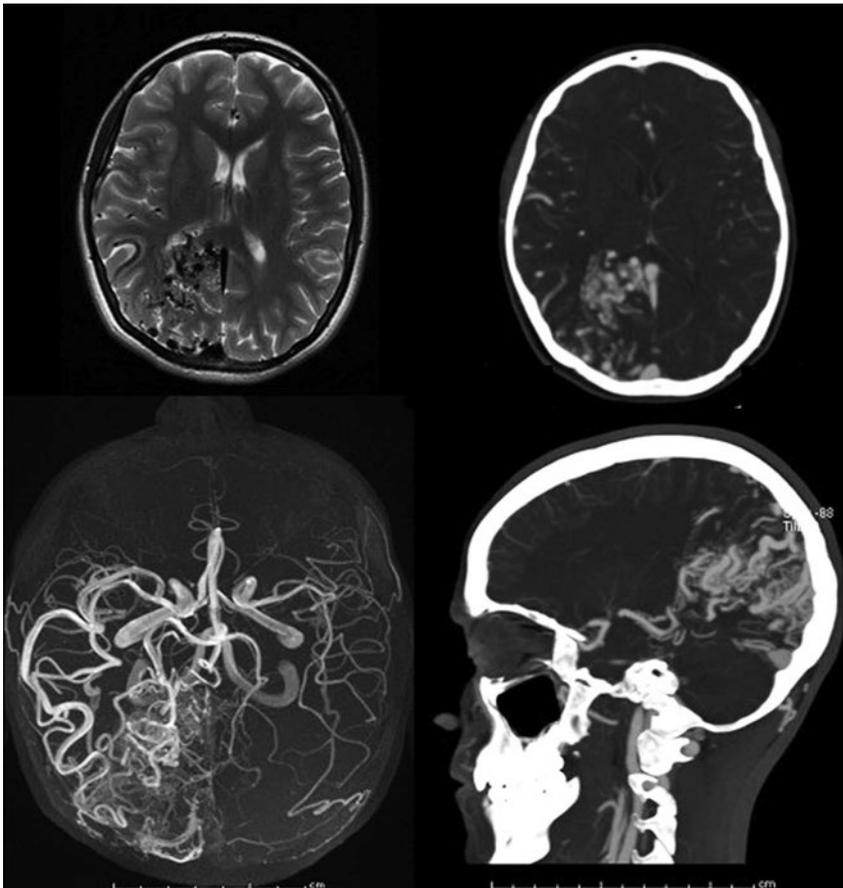

Fig. 67.1 Characteristics of an arteriovenous malformation on magnetic resonance (MR) imaging and computed tomography (CT). Upper left: Axial T2 MR image with dark flow voids evident in the right occipital pole. Upper right: Same lesion detailed by CT angiography. Lower right: Sagittal view of the lesion, demonstrating a wedge-shaped configuration. Lower left: A collapsed MR angiogram.

of various signal intensities corresponding to blood products in different stages of evolution and occasionally calcium and hemosiderin.^{37,38} The serpiginous shape of the vessels may be distinctive, identified as flow voids, and the relevant anatomy can be well visualized with MR angiography. Susceptibility imaging will sometimes disclose evidence of previous

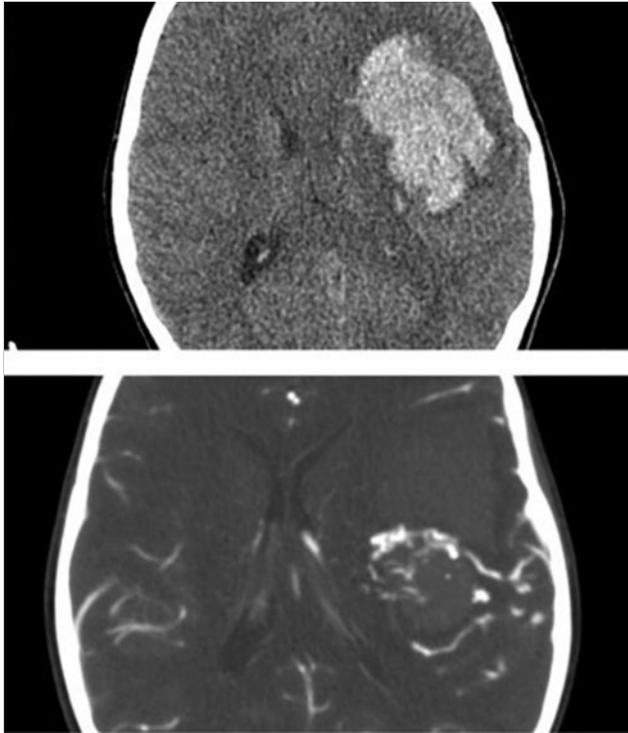

Fig. 67.2 Utility of computed tomographic (CT) angiography in an emergent setting. Upper image is a noncontrast axial CT scan showing a large left frontal hemorrhage. Lower image is a CT angiogram of the same patient revealing the relationship of an arteriovenous malformation to clot and serving to increase the safety of emergent clot removal.

hemorrhage as a dark “bloom” around the nidus.³⁹ Chronic ischemic changes, presumably a result of the “steal” phenomenon or venous hypertension, may be identified on MR imaging as bright signal of the surrounding brain on FLAIR (fluid-attenuated inversion recovery) or T2 images. The understanding of local ischemia can also be improved with diffusion–perfusion imaging.⁴⁰

Traditional digital subtraction angiography remains the definitive investigative technique for the evaluation of intracerebral AVM (► Fig. 67.3). It establishes the nature and extent of the lesion, in addition to its blood supply and venous drainage.⁴¹ Angiography generally includes bilateral injection of both the internal and external carotid arteries and the vertebral arteries in order to visualize all of the vessels supplying the AVM. Three-dimensional angiography with computer-generated reconstruction is increasingly employed to depict lesional anatomy. It is important to underscore that 15% of cerebral AVMs receive some blood supply from the ipsilateral or contralateral meningeal arteries.⁴²

The typical angiographic appearance of an AVM is that of distended, tortuous afferent and efferent vessels connecting with a tangled vascular mass, through which the circulation time is rapid (i.e., arteriovenous shunting). Angiography can fail to demonstrate an AVM despite suggestive findings on CT or MR imaging, usually because of the partial or complete thrombotic occlusion of feeding vessels. Other suggested causes of an angiographically occult AVM include small size, compression by adjacent clot, and destruction by hemorrhage. In the setting of an intracerebral hematoma without a clearly proximate cause, repeated MR imaging at 6 weeks after a hemorrhage is often recommended to screen for an occult AVM.^{35,36}

For those patients presenting with seizure, electroencephalography can be considered during the initial evaluation. Electroencephalography may show focal or lateralized abnormalities that suggest the presence of an underlying structural lesion. These findings should prompt further investigation, most commonly MR imaging.

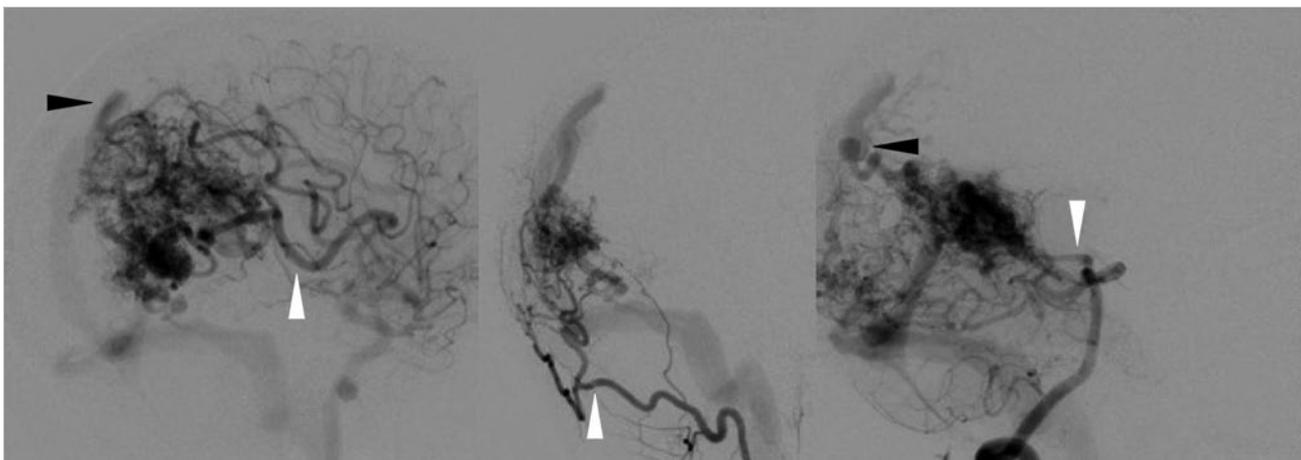

Fig. 67.3 Angiographic characteristics of arteriovenous malformation (AVM). Catheter angiography of the AVM from ► Fig. 67.1 reveals feeding arteries (*white arrowheads*) and draining veins (*black arrowheads*). Images include (from left to right) internal carotid artery, external carotid artery, and vertebrasilar injections. These studies highlight the need to perform multiple-vessel injections to identify all potential lesional vessels.

67.6 Indications for Surgical Treatment

67.6.1 Rationale for Intervention

The reasons for treating an AVM, particularly in children, are compelling. With each hemorrhage from an AVM, there is an approximately 25% chance that a permanent deficit or death will result, and children have an annual risk for hemorrhage of about 2%, a substantial cumulative risk for younger individuals with an expected long life span.⁴³ Treatment has the potential to reduce or eradicate the lifetime risk for hemorrhage and also has the potential to eradicate AVM-related comorbid conditions, such as seizures and neurologic deficits. The goal of therapy is complete obliteration of the AVM. Partial destruction does not confer protection from bleeding in the future.³³

In general, there is a consensus that intervention for patients with symptomatic lesions—particularly AVMs that have bled—is warranted. More difficult are those lesions that are found incidentally or that cause questionable symptoms. In these cases, the indications for treatment rest on weighing the risk of intervention against the risk of the natural history of the unruptured AVM. As discussed above, the risk for hemorrhage is incompletely understood, although some data suggest that AVMs in younger children are more likely to bleed over the course of a lifetime, increasing the impetus to treat. In addition to these studies, one can review the specific angioarchitecture of an individual lesion. Recent work has revealed that angiograms of pediatric AVMs can identify features that are associated with an increased risk for bleeding. Smaller AVM size, exclusively deep venous drainage, and an infratentorial location are specific angioarchitectural factors independently associated with an initial hemorrhagic presentation in children with AVMs, and the presence of these factors, even in an asymptomatic patient, may help to inform the decision to treat in selected cases.⁴⁴

The optimal management of AVMs is controversial in both adults and children. AVM can be treated by one of three modalities—resection, endovascular techniques, or radiosurgery—or with a combination of embolization and either radiation or surgery. Each has inherent benefits and limitations. For some complex lesions, such as those with a high (4 or 5) Spetzler-Martin grade (see below), careful observation may be the appropriate option. The wide variety of lesional anatomical features and patient risk profiles, coupled with the lack of standardized outcome measurements, makes comparisons among studies difficult, reflected by the minimal information provided in the recent American Heart Association guidelines for the management of stroke in children.⁴⁵ Outcome measures include the following: (1) radiographic obliteration of the lesion; (2) observer outcome scales (Rankin Scale or Glasgow Outcome Scale); (3) patient-generated quality-of-life data; and (4) rates of specific comorbid conditions (e.g., seizures, headaches). The objective of this section is to offer guidance on when to select surgical treatment and how to provide the best operative management of these lesions.

67.6.2 Goals of Surgical Treatment

The operative goal is complete removal of the lesion. The decision to resect an AVM is based on several factors: (1) eloquence

Table 67.1 Spetzler-Martin arteriovenous malformation grading system

Size	Points
0–3 cm	1
>3–6 cm	2
>6 cm	3
Location	
Non-eloquent cortex	0
Eloquent cortex	1
Deep venous drainage	
Not present	0
Present	1

of the cortical location (speech, motor function, sensation); (2) pattern of venous drainage; (3) size; (4) associated aneurysms; (5) recent hemorrhage; (6) clinical deterioration; and (7) risk for complications from other modalities of therapy (e.g., radiation injury to the developing brain).^{46,47} Several of these factors are combined in the Spetzler-Martin⁴⁸ grade, which incorporates eloquence of location, pattern of venous drainage, and size and is considered predictive of the outcome of surgical management (► Table 67.1).

67.6.3 Indications for Surgical Treatment of Simple Lesions (Low Spetzler-Martin Grade)

A series of 20 pediatric patients with Spetzler-Martin grades 1 to 3 AVMs were treated by resection.⁴⁹ Good recovery was achieved in 18 of 20 children (90%), and 1 death (5%) was related to prior hemorrhage. In addition to the clinical findings, radiographic outcomes were also evaluated; the radiographic obliteration rate was 89% (17 of 19). In another study, lesions with a low Spetzler-Martin grade were successfully treated by resection, whereas high-grade lesions were treated by radiosurgery.⁴⁷ Other investigators have also recommended resection for low-grade or small, surgically accessible lesions, citing the benefits of immediate protection from rebleeding and the avoidance of delayed radiation-related brain injury. At the same time, they caution about the need for further study of the indications for surgical intervention.⁵⁰

The safety and efficacy of resection are increased by preoperative embolization in selected patients, especially both children and adults with larger lesions.^{51–54} Preoperative embolization can reduce blood loss, shorten operative time, occlude vessels less accessible to the surgeon (e.g., deep feeding arteries), and decrease the size of the AVM.³³ Nevertheless, no prospectively controlled studies have compared resection with and without embolization.

Although randomized trial data are lacking, the combined literature of institutional experience strongly supports resection as a primary treatment for children with Spetzler-Martin grade 1 or 2 AVMs. The low postoperative morbidity rates in patients with low-grade lesions (ranging from 0 to 12%), along with high rates of complete obliteration (up to 100%), suggest that

delayed control, inherent to radiosurgery, may not be warranted.^{24,47,49,55} For comparison, a similar group of patients treated with radiosurgery alone had a reported 80% efficacy rate of lesion obliteration at 36 months, with 4 of 53 patients having recurrent hemorrhage after treatment.⁵⁶

67.6.4 Indications for Surgical Treatment of Complex Lesions (High Spetzler-Martin grade)

Complex lesions (as defined by a higher Spetzler-Martin grade) carry a substantially greater risk for children. Multimodality therapy of AVM has been advocated by several investigators.^{24,47,57,58} Neurointerventionalists, radiation oncologists, and neurosurgeons work together to determine the best strategy for a particular patient. With the use of a multimodality approach, angiographic obliteration rates of 92.9% have been reported. In carefully selected patients treated with resection alone, a cure rate of 100% has been achieved.⁴⁷

The decision process becomes controversial for patients with high-grade lesions. Preoperative embolization has been employed to decrease flow and occlude deep feeding vessels, maneuvers particularly helpful to facilitate resection. Embolization is rarely employed as the sole treatment for AVM, although the agent Onyx (Micro Therapeutics [Covidien], Mansfield, MA) has recently been used.^{50,59} Radiosurgery alone seems to protect against bleeding following radiographic obliteration. Others have argued that there is some protective effect even before total radiographic obliteration of the lesion.^{60,61}

In one report, outcomes following resection with or without adjunctive embolization were 100% excellent or good at 36 months.⁴⁷ These results are possible because some patients were excluded if they were considered to be poor surgical risks. Embolization can reduce the size of an AVM, making it more amenable to radiosurgery.⁵⁹ In patients treated with radiosurgery without embolization, overall outcomes of 91% excellent or good and mortality of 9% were attained. When embolization was used before radiosurgery, the outcomes improved to 100% excellent or good at 36 months.⁴⁷ The efficacy of the multimodality treatment of large, complex lesions is supported by the results in a group of 53 children, in whom a 58% cure rate was noted at 3-year follow-up for those with AVMs larger than 6 cm in diameter.⁶²

In summary, the high likelihood of obliteration, coupled with low complication rates, makes a convincing argument in favor of multimodality treatment of pediatric AVMs. It is our practice at Boston Children's Hospital to review cases in a multidisciplinary meeting to weigh the risks and benefits of intervention for AVMs. In general, high-grade lesions are treated only after a detailed review and a discussion of alternatives and risks with the family. It is not unusual to recommend observation for children with larger, high-risk AVMs (often defined as those with a Spetzler-Martin grade of 5 or 6).

67.7 Surgical Treatment

Once the decision to operate has been made, a series of steps are followed that involve the timing of the operation, perioperative management, and specific operative strategies. Although

the marked variations in the size, location, and presentation of AVMs in the pediatric population preclude the possibility of a single, stock approach to all lesions, core principles remain that can reduce the risks of surgery. These key points are summarized in this section.

67.7.1 Timing of Treatment

The urgency of treating an AVM depends on its presentation. In the case of asymptomatic lesions, treatment planning can proceed in an elective fashion because the hemorrhagic rate is relatively low, approximately 1 to 3% per year for an unruptured AVM. In the case of lesions that have bled, rebleeding rates are approximately 6% for the first 6 months and 3% per year afterward.^{20,63}

The treatment of an AVM that has already bled depends on the clinical findings and on the anatomy of the malformation. Elevated intracranial pressure may preclude definitive imaging of the lesion. Urgent surgical intervention is necessary if the child is acutely ill from a focal clot or from hemorrhage-related hydrocephalus. If formal angiography is not possible (because of the clinical presentation), then more rapid imaging of the vasculature, such as with CT angiography, is necessary for preoperative planning.⁶⁴

The surgical alternatives are decompression of the cranial vault by evacuation of clot and/or cerebrospinal fluid diversion to lower intracranial pressure. In such emergent situations in which the anatomy of the lesion is unknown, given the low rebleeding rates of the lesions, definitive treatment of the AVM can be postponed until the child is clinically stable and the complex anatomy of the AVM can be delineated by formal angiography. Care should be taken to remove clot only, with the vascular malformation left undisturbed. Surgical treatment is usually scheduled at a later time (days to weeks) after ictus, often after better imaging has been obtained.

Preoperative embolization of an AVM assists the surgeon by reducing the size and flow of the lesion. In addition, deep arterial feeders in difficult locations can be treated before craniotomy. Embolization should be scheduled within a short period of time, 0 to 72 hours, before the resection. Longer delay risks the formation of new feeding vessels and collateralization, which can jeopardize resection. (For the same reasons, a similar schedule should be applied for embolization before radiosurgery.)

67.7.2 Perioperative and Anesthetic Considerations

The risk for an AVM bleeding during the induction of anesthesia is unknown, but it is probably low.^{33,65} Proximal arterial AVM-related aneurysms may increase the risk for bleeding due to shifts in blood pressure. Therefore, the goal should be normotension and euvolemia throughout the period of anesthesia.

Perioperative antibiotic administration for 24 hours is recommended. The use of antiepileptic medications and corticosteroids is debatable. Confirmation of complete resection by angiography is recommended, either intraoperatively or in the immediate (24 hours) postoperative period. New postoperative neurologic deficits should be investigated promptly by CT (to

assess for hemorrhage or hydrocephalus) or by diffusion-weighted MR imaging (if ischemia is suspected).⁶⁶

There are concerns specific to the pediatric patient undergoing resection of an AVM. Infants have a physiologically small blood volume; they cannot tolerate even minimal blood loss during a procedure. In addition, the cardiac output can be severely altered.^{67–69} Intravenous (IV) lines should be secured before the operation, and packed red cells must be in the operating room.

At Boston Children's Hospital, we employ a standardized protocol for the operative management of children with AVM. Although it may not suit every institution, or every case, we offer it here as an example of a framework that minimizes variation and error (see box "Operative Management of Children with Arteriovenous M (p.891) alformation").

Operative Management of Children with Arteriovenous Malformation

- Preadmission evaluation and studies
 - MR imaging and MR angiography are performed with appropriate series for frameless stereotaxy.
 - A preoperative patient consultation with interventional neuroradiology, neurosurgery, and anesthesia is arranged.
 - The involved teams (interventional radiology, neurosurgery, anesthesia, nursing, and intensive care unit [ICU] staff) review the specific equipment needs, concerns for the individual case, and expected duration of the treatments.
- Peri-embolization management
 - General anesthesia is induced, including the placement of a radial arterial line, bladder catheter, and appropriate IV access (including large-bore IV lines in anticipation of subsequent surgery). The systolic blood pressure is kept at a normal level or 10 to 20 mm Hg lower (based on age, and in no case above 120 mm Hg).
 - Diagnostic angiography is performed, including superselective catheterization to define feeding vessels followed by embolization (if appropriate). The dose of contrast is limited to 7 mL/kg and the radiation dose to 1 Gy per session. Onyx is administered to a maximal dose of 1 mL/10 lb of patient weight.
 - Following the completion of embolization, children are kept intubated in anticipation of operation the following day. Patients are monitored in the ICU, and blood pressure parameters are maintained as through the embolization. Patients are kept sedated, although anesthesia can be lightened briefly to obtain a limited neurologic examination. Post-embolization imaging is limited to presurgical planning or cases in which specific clinical concerns exist (e.g., abnormal examination, difficulties with embolization).
- Surgical management
 - Patients are brought to the operating room from the ICU as the first case the following day and intubated, with bladder and appropriate-bore IV access as previously described. Particular attention is paid to temperature regulation, especially in smaller children, and a warming device, such as a Bair Hugger (Arizant [3M], Eden Prairie, MN), is commonly employed.
 - Before incision, blood products are delivered to the operating room, the operative microscope is draped, and a minimum of three suctions is made available in the operative field. IV

antibiotics are given. Specific instruments are reviewed, including AVM clips, retractors, and bipolar cautery (in particular, nonstick forceps, such as IsoCool [DePuy Synthes, Raynham, MA], are often employed). Frameless stereotaxy is registered and used to plan the incision. In cases of deep lesions, we often complement frameless stereotaxy with ultrasonography.

- The general principles of AVM resection are followed (division of feeding vessels before interruption of draining veins, avoidance of entering the nidus), but unique to pediatrics is the small circulating blood volume, so that careful measurement of blood loss and close communication with anesthesia are vital to minimize the likelihood of hypovolemia.
- Following resection of the AVM, the craniotomy is closed and the child is transferred to the angiography suite while still under anesthesia. The operating room and equipment are kept sterile in case there is a need to return for additional resection. High-quality angiography is performed. If residual lesion is identified, the child is brought back to the operating room for further resection, and this protocol is repeated (including angiography to confirm complete excision). If the angiogram reveals complete resection of the AVM, the child is awakened and brought to the ICU for recovery.
- Postsurgical management
 - After surgery, the child is managed in the ICU with an arterial line, IV fluids, and a bladder catheter. The child is awake, and a neurologic evaluation is performed every 1 to 2 hours. The blood pressure is liberalized to 10 to 20 mm Hg above the norms for age, although efforts are made to keep the child normotensive. Pain management is often critical to achieving this goal. Diet is advanced as tolerated. No imaging is obtained unless there are specific concerns.
 - Following discharge, children are brought back for follow-up at 4 to 6 weeks. An angiogram is obtained at 1 year postoperatively, and if the angiogram does not show evidence of residual or recurrent AVM, then the child is seen annually with MR imaging and MR angiography for 5 years.

67.8 Operative Technique

Given the wide variety of AVM sizes and locations, it is impossible to identify any single approach for AVM surgery. Specific approaches should be selected to maximize access to the lesion, avoid eloquent neurologic cortex (if possible), and afford the surgeon visualization of feeding and draining vessels to permit proximal control of blood flow.

67.8.1 General Principles

The operating room should be notified to prepare for surgery. It is generally helpful to call to the room (or to the operating room desk the day prior, if possible) to review positioning, medications, nurse staffing, and equipment needs. Equipment should include the operating microscope, multiple suctions, bipolar electrocautery, an array of AVM/aneurysm clips, a craniotome (drill), and a retraction system. Anesthesia should be consulted and appropriate measures taken to ensure that multiple large-bore IV lines are available and that adequate blood products are

in the room. It is helpful to have the microscope draped and clips selected and loaded before the case is started, if possible, so that quick access can be obtained should unexpected bleeding occur during opening.

67.8.2 Craniotomy

Adequate exposure is critical to AVM surgery. It is important not to make the craniotomy too small in order to visualize the lesion safely. The use of frameless stereotaxy and other intraoperative navigation adjuncts (such as ultrasound) can help to minimize risk in these operations. At the time of bone flap removal, it is important to try to avoid tears in the dura so as not to injure subjacent AVM vessels. When opening the dura, be cognizant of potential adhesions between the dura and vessels (► Fig. 67.4). In some cases, it can be helpful to leave dural remnants adherent to the lesion in place and cut around them to avoid tearing surface vessels.

It is common to encounter a tight brain upon opening the dura. Key maneuvers, such as elevating the head of the bed, mild hyperventilation, or the use of osmotic diuretics, may help resolve this problem. Draining the cerebrospinal fluid can be useful, but it is important not to tear vessels while doing so.

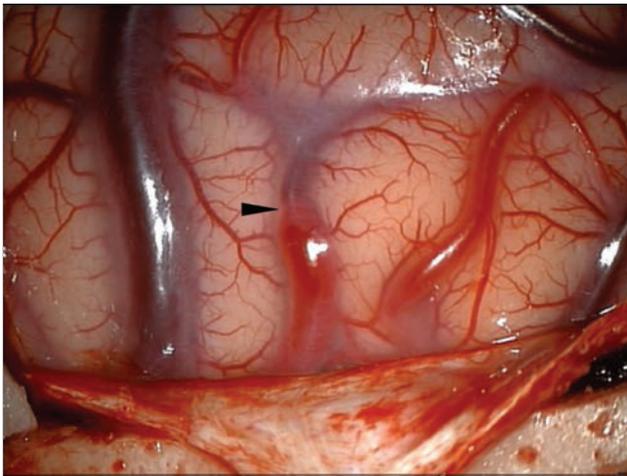

Fig. 67.4 Intraoperative cues for arteriovenous malformation (AVM) localization. Image of cortical surface as seen at the opening for an intraparenchymal AVM. Although the AVM is deep and not immediately visible on opening, an arterIALIZED vein (black arrowhead) gives warning of the lesion below and must be preserved during the initial dissection.

Once the dura is open, several general principles can be applied to nearly all AVM operations. These include:

- A primary surgical principle for AVM resection is the obliteration of feeding arteries before the occlusion of draining veins because premature closure of outflow can lead to unexpected AVM rupture with uncontrolled bleeding.
- AVMs are often wedge- or cone-shaped, and resection can be performed in a circumferential pattern, staying close to—but not entering—the nidus. It is helpful to try to maintain an even depth of resection around the lesion to avoid getting into a “hole,” and caution must be taken to minimize retraction on draining vessels during dissection (► Fig. 67.1, ► Fig. 67.5).
- Repeated inspection of the surrounding brain for swelling or bleeding can reduce complications by allowing the early identification of poorly placed retractors or clips.
- AVM vessels may coagulate poorly, and consideration should be given to clip application or gentle tamponade (if the bleeding is of small volume) if bipolar electrocautery is not working. Every attempt should be made to avoid operating within the nidus itself.

67.8.3 Closure

Inspection of the operative cavity for residual nidus is important, and perioperative angiography can be a useful adjunct to ensure complete resection. Evidence of brain swelling at closure may indicate occult bleeding, untreated hydrocephalus, or poorly compensated redistribution of blood flow, which can result in perfusion breakthrough hemorrhage. Causes of swelling should be thoroughly investigated and treated, if possible, before the patient leaves the operating room. The temporalis muscle and galea are closed with interrupted resorbable sutures, and the skin is closed with a running resorbable suture.

67.9 Postoperative Care

Postsurgical therapeutic maneuvers depend on the presentation. For a healthy child or a child who presents with chronic symptoms (seizure, developmental delay), often no immediate interventions are necessary (with the exception of antiepileptic medication if seizures are present). It is important to note that presentations can vary greatly in severity, and thus treatment has to be individually tailored. It is critical to discuss the management strategy for a patient after surgery with the ICU team

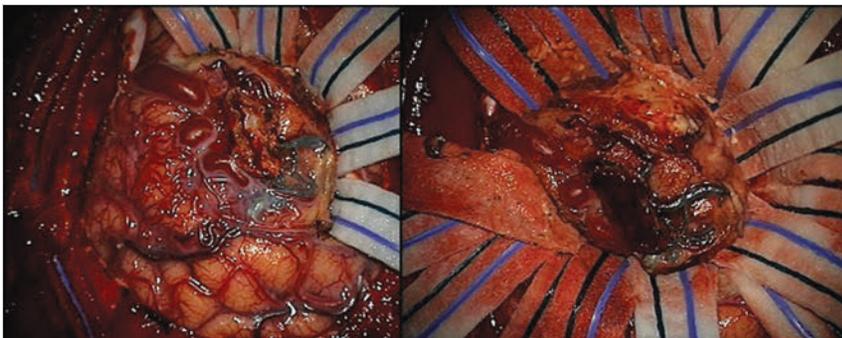

Fig. 67.5 Intraoperative images of a superficial cortical arteriovenous malformation (AVM). Initial image shows dilated draining veins (left). Subsequent image illustrates method of circumferential dissection around the AVM with preservation of the draining vein until the final portion of the case (right). Note the reduction in the caliber of the draining vein and the change to stagnant, deoxygenated venous blood after interruption of the arterial supply.

so that all members of the staff involved with the patient deliver consistent care.

► **Key points include:**

- Blood pressure should be controlled (labetalol or nifedipine) with the goal of normotension for age. However, in some cases with large or high-flow AVMs, a slightly lower than normal blood pressure may merit consideration to minimize the risk for perfusion pressure breakthrough hemorrhage in the immediate (24 to 48 hours) postoperative period.
- Control of the intracranial pressure with placement of an external ventricular drain and elevation of the head of the bed are warranted for a patient with hydrocephalus from hemorrhage.
- Antiepileptic medication should be given if there is concern for seizure.
- Steroids often are not needed (unless they are used as antiemetics).
- Frequent neurologic assessment with examination is important to detect changes that may warrant an imaging study to look for hemorrhage or stroke.

67.10 Treatment Alternatives

67.10.1 Radiation Therapy

Conventional fractionated radiation is not helpful in the majority of AVMs; however, stereotactic radiosurgery offers cure rates of up to 90% in lesions under 3 cm in size. This approach is beneficial for surgically inaccessible lesions or in patients who are high-risk surgical candidates. Shortcomings of this approach include a delay of up to 3 years for lesion obliteration (with unclear data on the changes in hemorrhage risk during this period) and exposure to radiation in children. Radiation has increased risk in younger populations, making its application less appealing in children less than 3 years of age.

Complications

The long delay between treatment and lesion obliteration in radiosurgery for AVMs means that the child is at risk for bleeding during this interval. Patients with small (<3 cm diameter), deep-seated lesions (in the basal ganglia, internal capsule, and thalamus) are the best candidates for radiosurgery. A study of 42 children with lesions in these locations documented a 62% angiographic cure rate within 2 years.⁷⁰ However, radiosurgery in these sites has shown a higher risk of rebleeding when compared to AVMs treated in other areas of the brain.⁷¹

Young children have risk of radiation-induced damage, including injury to the surrounding developing brain and potential for development of secondary malignancies. These risks limit radiation use to older children in most cases whenever possible.

67.10.2 Embolization

Although not traditionally used as a stand-alone treatment for AVMs other than in rare cases with a small nidus and a small number of feeding pedicles, there is a growing literature on the

use of newer embolization agents (Onyx) for definitive treatment of brain AVM in adults. However, the situation in children is more complex and embolization is rarely used as a stand-alone modality, as the recurrence rate is higher, and lesion immaturity may preclude complete visualization angiographically. Regardless, embolization is a significant aid in the treatment of AVMs, reducing their blood supply and facilitating operative approaches (usually <72 hours before surgery). Embolization also has a role in targeted treatment of non-operative lesions, by occluding areas at risk of hemorrhage, such as aneurysms or high-risk varices (those that are intraventricular).

67.11 Outcomes

67.11.1 Outcome after Surgery

Good recovery was achieved in 90% of pediatric patients with Spetzler-Martin grades 1 through 3 AVMs treated by resection,⁴⁹ and deaths occurred at a rate of 5%. Radiographic obliteration rate was 89%. Although level 1 or 2 data are lacking, the combined level 3 data strongly support resection as a primary treatment for patients with Spetzler-Martin grade 1 or 2 AVMs. The relatively low postoperative morbidity rates in patients with these lesions (ranging from 0 to 12%), along with a high rate of complete obliteration (up to 100%), suggests that delayed control, inherent to radiosurgery, may not be warranted.^{24,47,49,55}

67.11.2 Outcome after Nonsurgical Treatments

For comparison, a similar group of patients treated with radiosurgery alone had a reported 80% efficacy rate of lesion obliteration at 36 months, with 4 of 53 patients having recurrent hemorrhage after treatment.⁵⁶ One large pediatric AVM study included 40 patients and confirmed radiographic obliteration of the AVM nidus in 35% of the patients.⁷² The cumulative hemorrhage rate after treatment was 3.2% per patient per year in the first year and 4.3% per patient per year over the first 3 years.⁷² These rates of obliteration, which are notably lower than those reported in the adult population, were potentially complicated by the slightly larger than average size of the treated AVMs in the study group. In contrast, when 53 pediatric patients were stratified by AVM size (<3 cm³, 3 to 10 cm³, and >10 cm³), obliteration rates of 80% and 64.7%, respectively, were reported in the groups with the smallest and medium-size AVMs.⁵⁶

Although level 1 and level 2 data are lacking, the aggregate level 3 data strongly support the use of radiosurgery in the treatment of small (diameter <3 cm), deep-seated lesions in eloquent cortex. For Spetzler-Martin grade 1 and most grade 2 lesions, open resection is generally recommended rather than radiosurgery unless there are specific considerations that make resection unsuitable for the patient. Radiosurgery should be used only for larger lesions (grades 2 through 5) if the objective is complete obliteration of the AVM.³³

67.12 Complications

Bleeding is the most immediate complication of surgery, and risks are magnified in smaller children, who have little reserve.

The loss of one-quarter of the blood volume can induce shock, and there may be rapid decompensation in children, so that careful monitoring and replacement of blood products by the operative team are mandated.

Normal perfusion pressure breakthrough is a phenomenon that is thought to occur after the resection of high-flow AVMs; once the AVM has been removed, blood previously transmitted through the AVM is redirected to smaller, normal vasculature, with the subsequent inability of these vessels to handle the increased flow. This can result in brain swelling, increased intracranial pressure, seizure, neurologic dysfunction, or hemorrhage. The problem may be minimized by staged preoperative embolization and rigorous blood pressure control postoperatively.

Inadvertent occlusion of a normal cerebral artery can occur after embolization or after surgery. In this situation, the blood pressure should be increased temporarily in order to improve collateral supply to the ischemic region.⁷³ This maneuver does not appear to be associated with an increased risk for rupture of the AVM.³³

Neurologic deficit can occur following AVM resection, although specific rates are hard to derive, given the wide variability in AVM size and location.

Overall, postoperative morbidity rates in patients with low-grade (grades 1 through 3) Spetzler-Martin lesions are low (ranging from 0 to 12%) and rates of complete obliteration are high (up to 100%), suggesting that surgical resection of these lesions is warranted, especially when it is performed in experienced centers.^{24,47,49,55}

67.13 Follow-up

Recurrence of an AVM, particularly in the pediatric population, after angiographically confirmed obliteration, including the development of a lesion on the side opposite to the initial AVM, has been reported.^{16,24,47,74–77} AVMs in children may be physiologically different from those in adults, as suggested by their ability to expand and recur, which is possibly related to their expression of angiogenic proteins, such as vascular endothelial growth factor.⁷⁸ Therefore, careful follow-up of these patients is warranted, even after a normal postoperative angiogram. Although the timing of follow-up studies varies by practice, it is the policy in our institution to obtain MR images/MR angiograms at 6 months and an angiogram at 1 year.

67.13.1 Frequency of Office Visits

Postoperative care will frequently consist of an office visit approximately 1 month postoperatively, then annually thereafter. Radiation therapy also involves annual visits after treatment.

67.13.2 Frequency of Imaging

In addition to the perioperative angiogram to confirm obliteration of the AVM, MR images/MR angiograms at 6 months may be helpful as a baseline study, to then be used for comparison with subsequent annual MR images/MR angiograms. Imaging is performed annually for 5 years, if feasible. Digital subtraction

angiography is often performed at 1 year postoperatively to confirm durable cure.⁷⁹

67.13.3 Arteriovenous Malformations and Pregnancy

The treatment of a known AVM should be undertaken before pregnancy whenever possible. There are rare situations of a documented intracranial AVM in a pregnant woman. Either the AVM was not addressed before pregnancy or neurologic sequelae led to its discovery. Data in this small group of patients are inconclusive, particularly with regard to the rate of hemorrhage during the pregnancy.^{74,80–85} MR imaging is safe for initial evaluation of the anatomy of the lesion.⁸⁶ No specific recommendations can be made if the AVM is diagnosed during pregnancy because individual risk-to-benefit relationships need to be assessed. If the mother has an untreated or partially treated AVM, cesarean section should be considered.^{1,40,74,84,87}

Pearls

- The most important surgical decision is whether to operate or not. Whenever faced with an AVM, carefully weigh the risks and benefits of treatment—ideally in a multidisciplinary setting at an experienced center—before embarking on a course of action.
- Maximize the odds for success by formulating a detailed surgical plan. Obtain all imaging needed and review the relevant anatomical landmarks and angioarchitecture before going to the operating room. Understand the potentially risky areas of the resection and plan for possible emergencies.
- Engage your team. Use all resources at your disposal, including embolization, navigation, and the proper surgical tools. Most importantly, talk to your team—anaesthesia, nursing, and ICU staff—so that everyone is prepared for the case before, during, and after.
- During the operation, work from feeders to draining veins. Avoid entering the lesion, and try to tamponade bleeding instead of diving into the nidus. Maintain good lines of sight throughout the case, and frequently change views so as to avoid getting lost or overexposed in a deep hole. Move deliberately and with a plan at all times. Reinspect the brain routinely to make sure there is no unexpected bleeding or swelling out of your field of view.
- At the conclusion of the case, carefully inspect the cavity for residual lesion and consider angiography to confirm resection.

68 Radiosurgical Management of Cerebrovascular Malformations in Children

Douglas Kondziolka, Hideyuki Kano, and L. Dade Lunsford

Arteriovenous malformations (AVMs) of the brain are a common cause of hemorrhagic stroke in the pediatric population. In contrast to adults, in whom AVMs cause hemorrhage, seizures, headaches, and progressive neurologic deficits, the majority of children have an initial brain hemorrhage.^{1,2} Because of this risk for hemorrhage and its attendant morbidity and mortality, as well as the lifelong risks of an AVM should it go untreated, the majority of children with brain AVMs undergo some form of therapy. Rather than conservative management, treatment can include microsurgical resection, embolization, or stereotactic radiosurgery, alone or in combination.

Although they are considered to be congenital, it is unclear when brain AVMs actually develop.³ They are thought to develop in the fetus, but the rarity of presentation during the neonatal period has prompted some investigators to question whether AVM development only begins in utero, then progresses during the first years of life.⁴ This possibility also has been raised by various authors, who have noted the recurrence of childhood AVMs despite total resection confirmed by angiography.⁴⁻⁶ Others have noted the association between vascular malformations and tumors.⁷ Some are associated with aneurysms, venous sinus anomalies, or fistulas.⁸⁻¹³ Certainly some AVMs are detected shortly after birth, such as large parenchymal or vein of Galen malformations that present with congestive heart failure.¹⁴⁻¹⁶ Most AVMs are detected between the ages of 20 and 40 years, which may suggest latency in the evolution of the malformation. Perhaps some do evolve in their angioarchitecture, eventually posing a greater and greater risk for the patient.⁶ Nevertheless, 20% of AVMs entered into the first cooperative AVM study were diagnosed before the age of 20 years, and thus the childhood presentation of an AVM is not uncommon.¹⁷ In general, AVMs cause a significant proportion of pediatric strokes and are three times more likely than saccular aneurysms to cause intracerebral hemorrhage in persons younger than 18 years.²

68.1 The Natural History of Arteriovenous Malformations in Children

Matson declared that AVMs were the “most frequent abnormality of the intracranial circulation in childhood.”¹⁸ Because most children with AVMs undergo treatment, reports of untreated patients are too few in number for the natural history of untreated pediatric AVMs to be fully understood. In retrospective series, most authors found a hemorrhage rate at presentation higher than that reported for adults, usually in the range of 80%.^{19,20} In the 40-year Toronto experience published in 1992, Kondziolka et al reported on 132 children. Of these, 27 were managed conservatively, and death followed catastrophic hemorrhage in 13 of them. Of eight evaluable conservatively managed children, six were

normal, one had a seizure disorder, and one had a persistent neurologic deficit.⁶

In the entire Toronto series, the mortality rate from AVM hemorrhage was 25%. This high rate may have been related to a higher incidence of posterior fossa AVMs, in which the initial hemorrhage was often lethal. In the general referral population of the Toronto series, 31 children (24%) had a posterior fossa AVM, a feature that varied significantly from the cooperative study (32 of 453; $p < 0.0001$). At present, there is no evidence that AVMs in younger patients are more likely to lead to severe hemorrhage. It is likely that the pediatric mortality from hemorrhage is related to the higher percentage of AVMs with a deep brain location in children. Fufts and Kelly reported mortality in four of six patients who had posterior fossa AVM hemorrhages.^{21,22}

Ondra et al reported a 24-year AVM follow-up assessment in a Finnish population. They reported an annual hemorrhage rate of 4% (for patients with any presentation) and found no difference in hemorrhage rates related to patient age.²³ Pollock and colleagues performed a comprehensive analysis of AVM natural history hemorrhage risk.²⁴ In this study of angiographic and anatomical AVM criteria, the factors of a prior history of bleeding, a single draining vein, and diffuse AVM morphology were found to be significantly related to risk for hemorrhage. Based on these data, an individual patient with an AVM had an annual hemorrhage rate between 0.99 and 8.9%.²⁴ Although in that study age was not a significant variable, Mori et al reported a higher mortality from AVM-related hemorrhage in children than in adults.²⁵

Although these hemorrhage rates can be used in a discussion with patients or parents regarding brain AVMs, the actual use of such numbers to predict a risk over time is problematic. A simple risk prediction formula for natural history data that maintains each year of risk as independent can be used.²⁶ This formula is as follows:

$$\text{risk for hemorrhage} = [1 - (\text{chance of no hemorrhage})]^{\text{expected years of remaining life}}$$

Thus, for a 15-year-old patient with a 3% annual AVM hemorrhage risk and an expected 62 years of life remaining (according to insurance tables),

$$\text{risk for hemorrhage} = (1 - 0.97)^{62} = 85\%.^{27}$$

Although this formula assumes population homogeneity and a uniform natural history among persons of different ages, it is simple and useful for helping patients and parents understand the lifelong risks associated with untreated AVMs (► Table 68.1).²⁶

It is important to remember that conservative management is rarely advocated for children with brain AVMs. Gerosa et al warned that the poor results (18 of 56 cases) after conservative management in their series indicated that AVMs should be treated, regardless of the mode of presentation.²⁰ Itoyama et al in their natural history study found better outcomes in children younger than 15 years, emphasizing the great capacity of the

Table 68.1 Lifetime risk for arteriovenous malformation hemorrhage

Age at initial presentation (y)	Estimated years to live ^a	Lifetime risk for hemorrhage (%) (2%/y)	Lifetime risk for hemorrhage (%) (4%/y)
0	76	79	96
5	71	76	95
10	66	73	93
15	62	71	92
20	57	68	90

^aEstimates according to 1992 preliminary life tables prepared by the Metropolitan Life Insurance Company (MetLife), New York City.

pediatric brain to recover from stroke.²⁸ In general, the lifelong risk for hemorrhage mandates therapy in most children because the benefits of AVM removal or obliteration outweigh the therapeutic risks entailed. Although some children may wait for several years until they reach an age more suitable for treatment (e.g., we would rarely perform radiosurgery on a child younger than 2 years), observation usually is recommended only when a multimodality approach would have little chance to provide complete obliteration or improvement of neurologic function.

When AVMs are large (Spetzler-Martin grade 5), embolization, radiosurgery, or microsurgery alone, or a combination of these techniques, is not likely to cure significant numbers of patients; it is therefore reasonable to consider conservative management for these children. This is not to say that a large AVM cannot be cured, but the patient must carefully understand the risks involved in this stepwise approach before embarking on a program that may not provide great benefit. We have explored staged-volume radiosurgery for symptomatic patients who have large, critically located AVMs. With this approach, different anatomical components of the AVM are irradiated at 3- to 6-month intervals so that each component receives a high dose; however, the risks can be lessened by reducing regional irradiation and allowing repair of the sublethal effects of radiation.

Factors like location in the brain, arterial supply, suitability for embolization leading to volume reduction, lack of relationship of the AVM with critical functional brain, and well-defined nidus must all be understood as well as possible before treatment is selected. Nevertheless, it is often not possible to know what embolization can accomplish without placement of a catheter and a superselective angiographic assessment. Similarly, it is difficult to know how the brain may respond to surgical resection in individual patients. These variables are complex for patients with large AVMs. Although our understanding of the potential risks of these different treatments has improved, dilemmas remain for both patients and physicians in the choice of specific therapies.

68.2 Stereotactic Radiosurgery

In the late 1980s, stereotactic radiosurgery became an important therapeutic option for children with brain AVMs.²⁹ Radiosurgery is the single-session delivery of a focused volume of radiation to a defined intracranial target. This surgical option has significantly expanded our options in individual patients.

Table 68.2 Brain location of pediatric arteriovenous malformations treated with radiosurgery at the University of Pittsburgh

Brain location	Number	Percentage (%)
Frontal lobe	21	16
Parietal lobe	14	10
Temporal lobe	20	15
Occipital lobe	19	14
Corpus callosum	5	4
Thalamus	22	16
Basal ganglia	16	12
Pineal region	1	0.7
Cerebellum	5	4
Brainstem	14	14

1	3	2.2
2	34	25.2
3	58	43.0
4	17	12.6
5	3	2.1
6	23	17.0

Before stereotactic radiosurgery, the options were surgical resection, embolization, and conservative management.²⁷ Many patients continued to have a patent AVM and a risk for hemorrhage. Radiosurgery provided a new therapeutic approach for the management of deeply located malformations in high-risk locations.^{30–34} The increased number of radiosurgical facilities worldwide has been followed by increased use of this technology for pediatric AVMs. During a 17-year interval, we performed Gamma Knife radiosurgery in 159 children with brain AVMs: 85 boys and 74 girls with a mean age of 12 years (range, 2 to 17 years). Indications for radiosurgery included all types of clinical presentation, any brain location, and an AVM diameter of less than 3.5 cm (► Table 68.2). Some families chose radiosurgery over resection for “operable” AVMs in their desire to avoid craniotomy. Most of these children had small AVMs with a nidus that might have been difficult to locate during surgery (► Table 68.3).

68.2.1 Technique

Most children younger than 13 years receive general anesthesia for radiosurgery. Older children usually require light intravenous sedation. Before radiosurgery, patients and parents speak to the neurosurgeon, radiation oncologist, and radiosurgical nurse regarding the procedure and watch a teaching video tape. Children typically tolerate skull frame fixation well. We use the

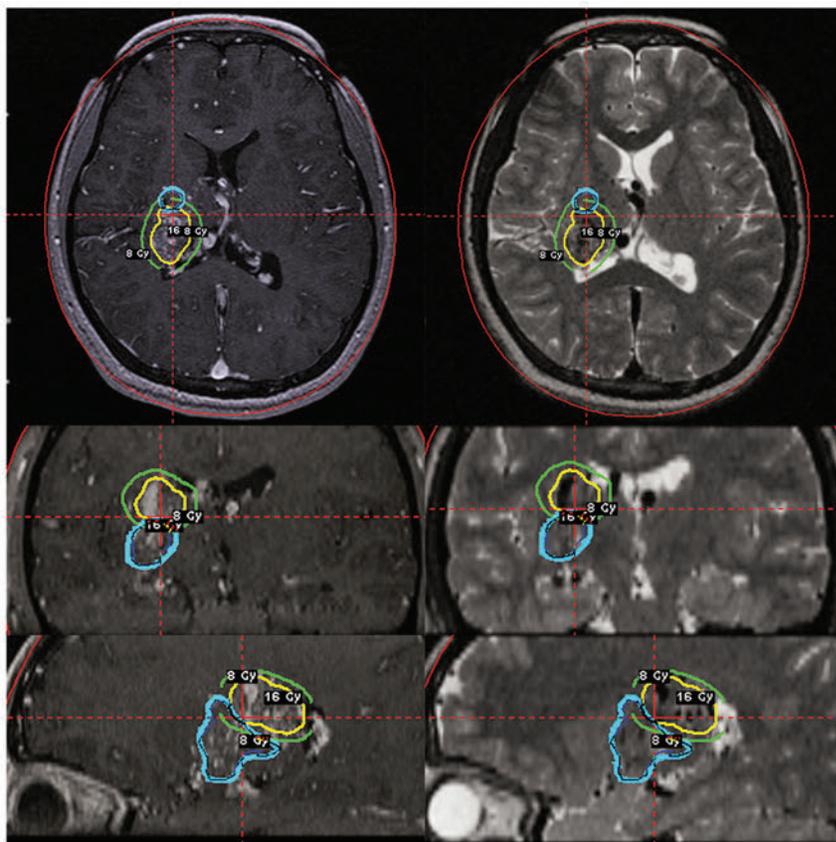

Fig. 68.1 Volume-staged gamma knife radiosurgery plan (16 Gy to the 50% isodose line) for a 12-year-old girl with a thalamic arteriovenous malformation. Axial (upper), coronal (middle), and sagittal (lower) T1-weighted contrast-enhanced and T2-weighted magnetic resonance images showing an anatomical component of the first (blue line) and the second (yellow) volume-staged stereotactic radiosurgery.

Leksell model G stereotactic frame (Elekta, Atlanta, GA), which is applied to the outer table of the skull with four-point fixation. The frame is shifted toward the side of the malformation in an attempt to bring the AVM close to the center of the stereotactic space. Patients then undergo contrast-enhanced stereotactic magnetic resonance (MR) imaging with both short TR (time to repetition) imaging and volume acquisition SPGR (spoiled gradient recalled) sequences, used for MR angiographic reconstruction.³⁵ The majority then undergo stereotactic angiography, with all images transferred digitally to a high-speed computer workstation (► Fig. 68.1 and ► Fig. 68.2).

Radiosurgical dose planning is performed by the neurosurgeon in conjunction with the radiation oncologist and medical physicist. For AVMs with an irregular volume, multiple isocenter plans are created in order to conform the AVM nidus margin to the selected treatment (usually the 50% isodose). The maximal dose is selected based on the weighting of various factors, such as AVM volume, brain location, and pertinent clinical history. With use of the integrated logistic formula (which predicts a 3% risk for permanent radiation-related complications), the appropriate margin dose is selected. We attempt to choose an effective and tolerated dose, balancing the highest obliteration rates achievable with risk factors related to volume and location. Single or multiple isocenter radiation is then performed with the Gamma Knife (Elekta Instrument, Atlanta, GA). As a last step, the stereotactic frame is removed and a local dressing is used to wrap the head. The patient is transferred either to the recovery room (if general anesthesia was required) or back to the hospital room (if local anesthesia was used). All patients are

discharged home the next day. Therapeutic anticonvulsant agents are administered to patients with lobar AVMs. A single intravenous dose of methylprednisolone is administered immediately after radiosurgery.

For follow-up, we obtain MR images at 6- to 12-month intervals after radiosurgery in order to assess both the vascular and the parenchymal response. An angiogram is requested for all patients beginning 3 years after radiosurgery. When complete obliteration or only an early draining vein is identified on the follow-up angiogram, no further treatment is necessary. For patients who have small residual AVM nidus more than 3 to 3.5 years following radiosurgery, additional treatment is usually required to complete the obliteration. This may involve either microsurgical resection or repeated radiosurgery.

68.3 The University of Pittsburgh Experience

In the University of Pittsburgh pediatric series, 87 patients (64%) presented with a hemorrhage, 16 (12%) had headache, and 20 (15%) had experienced prior seizures. Extraocular movement dysfunction was noted in 1 (0.7%) and hand intention tremor in 1 (0.7%). In 10 patients (7%), the diagnosis was made by imaging during the evaluation of a problem unrelated to the AVM. A neurologic deficit was present in 54 patients (40%) at the time of radiosurgery. Prior subtotal surgical resection (range, 1 to 4 operations) had been performed in 22 children (16%). Embolization was performed in 25 patients (19%) in an

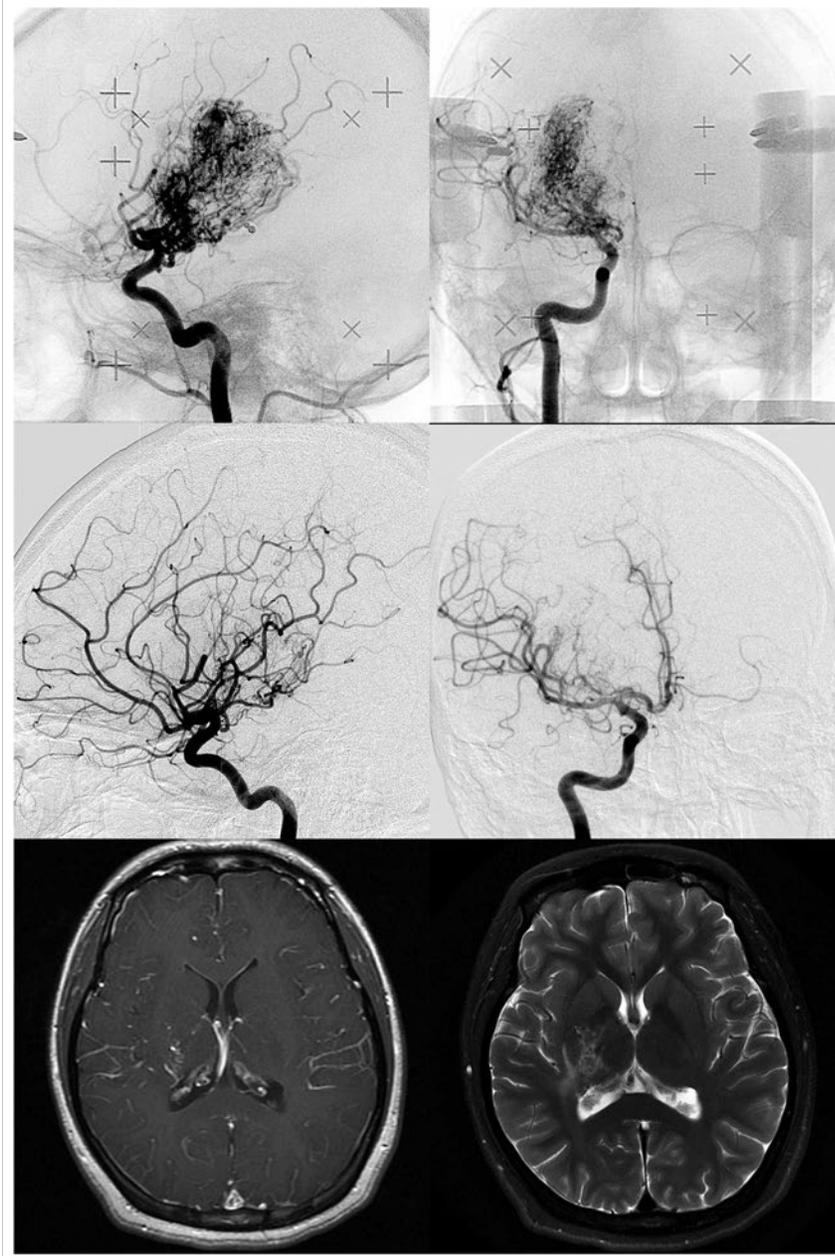

Fig. 68.2 Upper: Angiograms showing a 12-year-old girl with a thalamic arteriovenous malformation at the time of Gamma Knife radiosurgery. Middle: Angiograms showing total obliteration 38 months after a second volume-staged radiosurgery. Lower: Axial T1-weighted contrast-enhanced and T2-weighted magnetic resonance images showing total obliteration with a slight abnormal area on the T2-weighted image.

attempt to reduce the size of the AVM before radiosurgery. The AVMs were located in the cerebral hemispheres in 74 patients, the cerebellum in 5, the corpus callosum in 3, the thalamus in 22, the basal ganglia in 16, the pineal region in 1, and the brainstem in 14. A Spetzler-Martin grade 1 AVM was diagnosed in 3 (2%), grade 2 in 34 (25%), grade 3 in 58 (43%), grade 4 in 17 (13%), grade 5 in 3 (2%), and grade 6 in 23 patients (17%).

The mean AVM volume in this series was 2.5 mL (range, 0.1 to 17.5 mL). The median number of isocenters was 4 (range, 1 to 17). The median dose selected to the AVM margin was 20 Gy (range, 15 to 25 Gy), and the median maximum dose was 40 Gy (range, 30 to 50 Gy). In general, an AVM margin dose of 23 to 25 Gy was delivered if possible. This dose range has been associated with the highest obliteration rate in published studies.³⁶ The selected dose is not specifically lower for children than for adults, but attention is paid to AVMs near the

hypothalamic-pituitary axis before radiosurgery is chosen as a treatment. We limit irradiation of the pituitary region in an attempt to avoid risks for growth delay. The risk for an AVM hemorrhage is neither increased nor decreased by radiosurgery until complete obliteration has occurred.³⁷

68.3.1 Arteriovenous Malformation Obliteration

In our study,³⁸ obliteration rates after radiosurgery documented by either angiography or MR imaging criteria were 45%, 64%, 67%, and 72% at 3, 4, 5, and 10 years, respectively, with a median of 71 months of follow-up. The median time until documentation of total obliteration on MR imaging was 37 months. In 81 patients with 4 years or more of follow-up, 57 patients

(70%) had total obliteration documented by angiography. Factors associated with a higher rate of documentation of AVM obliteration were smaller AVM target volume, smaller maximum diameter, and larger margin dose.

Tanaka et al compared their results after Gamma Knife radiosurgery in 23 children and 76 adults whose mean AVM volumes and margin doses were similar. They found 1-year complete obliteration rates of 74% in children and 45% in adults, and 2-year complete obliteration rates of 95% and 81% in children and adults, respectively.³⁹ These data lend further support to the concept of a higher obliteration rate in children. Pan et al⁴⁰ reported that AVM obliteration was achieved in 48 (65%) of 74 pediatric patients at 4 years after initial stereotactic radiosurgery. Additional stereotactic radiosurgery, when needed, led to an overall total obliteration rate of 81%.

68.3.2 Risk for Hemorrhage after Radiosurgery

In the previous series, the annual hemorrhage rate for pediatric AVMs after stereotactic radiosurgery ranged from 0.56 to 3.2%.^{33,40–45} In our study,³⁸ 8 patients (6%) had a hemorrhage during the latency interval, and 1 patient died. The rates of AVM hemorrhage after stereotactic radiosurgery were 0%, 1.6%, 2.4%, 5.5%, and 10.0% at 1, 2, 3, 5, and 10 years, respectively. The overall annual hemorrhage rate was 1.8%. Larger-volume AVMs were associated with a significantly higher risk for hemorrhage after stereotactic radiosurgery. No patient bled after documentation of AVM obliteration with either MR imaging or angiography. A larger target volume was associated with higher rate of hemorrhage after stereotactic radiosurgery.

68.3.3 Results for Arteriovenous Malformations Causing Seizures

Seizures are the second most common presenting symptom of vascular malformations, occurring in 15 to 20% of cases. For children with seizures related to an AVM, the goal of radiosurgery is both AVM obliteration and cessation of seizures. Gerszten et al reviewed our experience in children younger than 18 years who had radiosurgery for AVMs that caused seizures.⁴⁶ Before radiosurgery, 13 children had seizures; seven had a single seizure and six had multiple seizures. Two children had intractable simple partial seizures. Six patients also had an intraparenchymal hemorrhage. Previous treatments included partial surgical resection (n=3) and embolization (n=7). At 1 year after radiosurgery, 11 of the 13 children (85%) with seizures were seizure-free and required no anticonvulsant therapy. Two of these children had a single generalized tonic-clonic seizure after radiosurgery and were found to have subtherapeutic levels of anticonvulsant medication. Both were later successfully weaned from medication. Two patients had a significant decrease in the frequency and severity of simple partial seizures but did not become seizure-free. No difference was found between seizure outcome in children with complete obliteration of their AVM and that in children with residual AVM at follow-up of at least 1 year.

It is still not known whether complete removal or obliteration of an AVM leads to consistent control of seizures. Also, no relationship has been established between the occurrence of a

preoperative bleed and the likelihood of its causing or aggravating a seizure disorder afterward. In adult radiosurgery series, good seizure control occurs in more than 70% of patients; better results are identified with increasing age and a higher dose of radiation.⁴⁷ Because the neural tissue surrounding the AVM, not the lesion itself, is the epileptogenic focus, the effect of radiosurgery on the surrounding brain may be related to hemodynamic effects, local irradiation, or some other factor. Some effect of radiosurgery on the brain surrounding the AVM, perhaps improvement of regional brain perfusion, may diminish the neuronal epileptogenic potential. Because the outcome of a child with a seizure disorder may be different from that of an adult with seizures, in terms of both social and intellectual development, an attempt to obtain complete control of seizures without medications is warranted in all patients. Whether surgical extirpation, radiosurgery, or embolization is necessary remains to be determined in individual patients. Children with intractable seizures and an AVM might benefit from inclusion in a preoperative epilepsy protocol in which a combination of approaches could further improve seizure outcome. Because radiosurgery is used for both “resectable” and “unresectable” AVMs, comparisons between outcomes after radiosurgery and those after resection are warranted.⁴⁸ Knowledge of the anatomical lesion (AVM) and the functional lesion (epileptic focus) likely is probably necessary to obtain an even higher rate of seizure control.

68.3.4 Morbidity of Radiosurgery

Early complications after radiosurgery are rare. Some children may experience brief nausea after anesthesia. All patients have been discharged from the hospital within 24 hours. An immediate postoperative seizure has been rare in our experience since we instituted a protocol of preoperative anticonvulsant agents in patients with subcortical lobar AVMs.

As AVM obliteration occurs, parenchymal changes can be identified on serial imaging studies that may or may not be symptomatic, depending on location in the brain.⁴⁹ Brainstem AVMs are associated with a higher incidence of complications than supratentorial AVMs.^{50–52}

Long-term results are especially important for children and young adults. In our series,³⁸ eight patients (6%) developed adverse radiation effects after stereotactic radiosurgery at a median of 6.6 months (range, 2.8 to 13.2 months). Permanent neurologic deficits developed in two of six patients. A factor associated with a higher rate of symptomatic adverse radiation effects was an AVM location in the brainstem, thalamus, or basal ganglia. Delayed cyst development was diagnosed in one patient (0.7%) with a prior hemorrhage at 56 months after stereotactic radiosurgery, but no additional treatment was required. Yamamoto et al reported the occurrence of cystic parenchymal changes years after AVM obliteration, and we have seen this in two patients in our series.⁵³ We have not noted a delayed radiation-induced malignancy in our experience of 12,000 patients managed for various disorders.

68.3.5 Role of Embolization before Stereotactic Radiosurgery

Embolization of larger-volume AVMs is sometimes performed before stereotactic radiosurgery in an effort to increase the

probability of complete obliteration.^{21,29,54} The goal of embolization is quite specific when it precedes radiosurgery: permanent volume reduction. Recanalization of a portion of an embolized AVM that lies outside the irradiated volume will place the patient at continued risk for bleeding. Of 45 patients who underwent repeated AVM radiosurgery at our center, 19 (42%) had previously undergone one or more embolization procedures to reduce the volume of the AVM.⁵⁵ Of these 19 patients, 3 (16%) required second-stage radiosurgery because a portion the embolized AVM recanalized after radiosurgery. Recanalization of AVMs has been observed with both acrylates^{56,57} and polyvinyl alcohol.^{58,59} Lasjaunias et al stated that they have not observed recanalization of an AVM at later follow-up when the angiographic findings at 6 to 12 months were strictly normal.⁶⁰ Embolization also has the potential to divide an AVM into multiple compartments, which can make conformal dose planning difficult.^{14,29} Multivariate analysis has shown prior embolization to be a negative predictor of successful AVM radiosurgery.⁶¹ As a result, we are using embolization before radiosurgery less frequently in the management of larger-volume AVMs.

68.4 Cavernous Malformations of the Brain

Cavernous malformations can occur sporadically or as an autosomal-dominant familial disorder. They are composed of endothelial cell-lined sinusoids without intervening brain tissue. Although most cavernous malformations are identified in adult patients with minimal or no symptoms when an imaging study is performed, children who have cerebral cavernous malformations usually are symptomatic. Related symptoms can include brain hemorrhage, seizures, and focal neurologic deficits.⁶² Multiple cavernous malformations usually are seen as part of a familial disorder. In this setting, parents and siblings should undergo imaging studies for both genetic counseling and the identification of specific lesions. It may also be that cavernous malformations develop over time, perhaps first as a microscopic lesion that through repeated microhemorrhage slowly enlarges and subsequently becomes apparent on an imaging study. Mixed cavernous and venous malformations can also occur, with symptoms referable to bleeding or regional venous hypertension.⁶³ Horowitz and Kondziolka identified increasing numbers of malformations within different generations of the same families studied with MR.⁶⁴

Cavernous malformations that are incidentally recognized have a low annual rate of bleeding. In a large prospective natural history study, Kondziolka et al identified a 0.6% annual hemorrhage rate in patients without a prior symptomatic hemorrhage.⁶⁵ This finding occurred regardless of age, brain location, or type of presentation (i.e., seizures or headache). However, in patients who had sustained a prior symptomatic hemorrhage, the subsequent annual hemorrhage rate was a magnitude higher, with a 4.5% annual risk for bleeding.⁶⁵ Thus, children who are found to have a symptomatic cavernous malformation often will require treatment. For those with a single symptomatic lesion, surgical resection should be performed when the malformation is located in a brain region where resection is feasible. If the lesion is contained entirely within the

substance of the thalamus or brainstem, resection may not be appropriate. We have used radiosurgery in both children and adults when prior multiple hemorrhages and a deep brain location mandated treatment.^{66,67} In this setting, radiosurgery was associated with a significant reduction in the hemorrhage rate over time, especially after a 2-year latency interval.⁶⁸ However, the lack of an imaging test that confirms cure and the potential morbidity of radiosurgery in the brainstem or thalamus argue for its use only in symptomatic patients with malformations in critical locations. To date, 12 children with cavernous malformations have had radiosurgery at our center (mean age, 11 years), with a median of 2 symptomatic hemorrhages per patient (range, 1 to 10).⁶⁹ Brain locations included the pons/midbrain (n=6), thalamus,¹⁹ and frontal, parietal, occipital, and temporal lobes (1 in each). The mean radiosurgery margin dose was 15.6 Gy. One patient had 3 symptomatic hemorrhages within 2 years after stereotactic radiosurgery. One patient had 1 symptomatic hemorrhage 2 years after stereotactic radiosurgery. The other 8 patients did not have hemorrhage after stereotactic radiosurgery at a median follow-up of 3 years.

68.5 Venous Malformations (Anomalies)

Venous malformations are congenital anomalies of the venous circulation. Although they are developmental anomalies, they provide drainage of normal brain tissue. Venous malformations usually are located between the deep and superficial venous systems. Common brain locations include the cerebellar hemispheres, brainstem, basal ganglia, frontal lobe, and parietal lobe. Often, venous malformations are diagnosed as an incidental finding on a computed tomographic scan, MR image, or angiogram. There has been no consistent relationship between venous malformations and headaches. Even in patients who present with seizures and are found to have a venous malformation, a causative link is difficult to identify. Some investigators have found that the epileptogenic focus identified by electroencephalography is anatomically separate from the venous malformation.⁷⁰ Thus, a specific treatment directed at the venous malformation in some patients may not relieve symptoms.

In several natural history studies, venous malformations have been associated with extremely low annual hemorrhage rates.⁷¹ Although they are occasionally associated with hemorrhage (perhaps when they coexist with a cavernous malformation), resection of a venous malformation usually is not warranted. In the setting of a large hemorrhage in a noncritical location, the venous malformation and hematoma can be removed with relatively low risk. The surgeon must remember that resection of the venous malformation will eliminate the venous drainage from that brain region. If the brain region is critical, then a symptomatic venous infarction may occur. For this reason, many surgeons would evacuate only the hematoma and leave the venous malformation intact. Rothfus et al reported the resection of cerebellar venous malformations in children who had sustained hemorrhages.⁷² Adverse outcomes due to brain edema have been reported after the use of radiosurgery for venous malformations.⁷³ In general, these functional venous anomalies should be ignored, although they are of clinical and imaging interest.

Pearls

- For most children older than 12 years, radiosurgery can be performed with intravenous sedation and local anesthesia.
- Endovascular embolization immediately after radiosurgery can be used in selected patients to eliminate specific hemodynamic risk factors, such as aneurysms.
- Repeated or staged radiosurgery procedures may be required to achieve total AVM obliteration with significant reduction of risk for hemorrhage.
- Stereotactic radiosurgery for cavernous malformations and AVMs in cortical locations can be associated with a significant reduction in risk for hemorrhage over time.
- Radiosurgery is not an appropriate therapeutic choice for a patient with a cerebral venous malformation. Such deep venous anomalies should be left alone.

69 Vein of Galen Aneurysmal Malformation

Alejandro Berenstein and Yasunari Niimi

Vein of Galen aneurysmal malformation (VGAM) is a rare vascular malformation involving the embryonic precursor of the vein of Galen. “Vein of Galen malformations” are reported to account for fewer than 1% of all arteriovenous malformations (AVMs) in the cooperative study of subarachnoid hemorrhage.^{1–3} However, the true incidence is difficult to determine because significant diagnostic confusion exists among the various malformations that involve or drain into the vein of Galen or its embryonic precursor, the median vein of the prosencephalon. We define VGAM as a purely fistulous AVM draining to the median vein of the prosencephalon. Other vascular lesions that cause dilatation of the true vein of Galen are defined as vein of Galen aneurysmal dilatation (VGAD) or vein of Galen varix (VGV). VGADs are a group of malformations that drain pial or dural shunts into the true vein of Galen or its tributary and are associated with dilatation of the vein of Galen. VGV is a dilated vein of Galen without arteriovenous (AV) shunts. We describe the vascular anatomy, types, clinical manifestations, natural history, treatment, and outcome of VGAM and its distinctions from VGAD and VGV.

69.1 Vascular Anatomy

Raybaud et al⁴ reported in 1989 that the dilated midline vein in VGAM is not the true vein of Galen but its embryologic precursor, the median vein of the prosencephalon. Based on analysis of the vascular anatomy of VGAM and vascular embryology, a VGAM likely forms within an embryonic stage of 21 to 23 mm (6 weeks) and 50 mm (11 weeks), during the time when the vein of Galen and straight sinus normally develop from a transient precursor, the median vein of the prosencephalon.⁴

Therefore, a true vein of Galen does not exist in VGAM. Moreover, in VGAM, the median vein of the prosencephalon drains only AV shunts. In VGAM, the normal deep cerebral structures drain through alternate venous pathways, typically through a vein that has an epsilon shape on the lateral view of a cerebral angiogram.^{5,6} Further drainage of the malformation is in most cases through the embryonic falcine sinus (precursor of the straight sinus) to the superior sagittal sinus. A straight sinus is usually absent, and persistence of other embryologic sinuses, such as occipital and marginal sinuses, is frequently observed in patients with VGAMs. Persisting arterial anomalies such as a limbic arterial ring involving the anterior and posterior choroidal arteries and pericallosal arteries are also frequently present.

The AV fistula in VGAM can be single or multiple. Arterial anastomoses between feeding pedicles are often seen. Two subtypes of VGAM, choroidal and mural, can be distinguished.

69.2 Classification

69.2.1 Choroidal Vein of Galen Aneurysmal Malformation

In choroidal VGAM (► Fig. 69.1), multiple fistulas are located in the subarachnoid space in the choroidal fissure. These multiple

fistulas communicate with the anterior aspect of the median vein of the prosencephalon. The arterial feeders are usually bilateral anterior and posterior choroidal arteries, a subforniceal branch, pericallosal arteries, and subependymal branches of thalamoperforators. This type of VGAM usually causes high-output cardiac failure in newborns because of the presence of multiple high-flow fistulas with less outflow restriction than in the other type of VGAM. This type of VGAM can be recognized by its complex arterial network and is the more aggressive manifestation of the disease. These lesions are more challenging to treat because of comorbid severe cardiopulmonary failure.

69.2.2 Mural Vein of Galen Aneurysmal Malformation

In mural VGAM (► Fig. 69.2), the fistula is located in the subarachnoid space in the wall of the dilated median vein of the prosencephalon, usually along its inferolateral margin. The vessels supplying the shunt are usually the collicular and/or the posterior choroidal arteries and may be unilateral or bilateral. In contrast to the choroidal-type VGAM, the mural type has fewer fistulas and typically has more outflow restriction, which leads to dilatation of the median vein of the prosencephalon but may protect against high-output cardiac failure. The mural type of VGAM, therefore, clinically presents later in infancy with macrocephaly or failure to thrive and may be associated with mild cardiac failure or asymptomatic cardiomegaly.

69.2.3 Vein of Galen Aneurysmal Dilatation

In contrast to VGAM, the midline ectatic vein in this group of lesions is the true vein of Galen. The vein of Galen, therefore, receives drainage from normal brain as well as from the malformation. Two types of VGAD, parenchymal and dural, can be distinguished.

Parenchymal Arteriovenous Malformation with Vein of Galen Aneurysmal Dilatation

Parenchymal VGADs (► Fig. 69.3) are subpial brain AVMs that drain into a tributary of the vein of Galen. Aneurysmal dilatation of the vein of the Galen is secondary to an outflow obstruction. Outflow obstruction develops in many pediatric fistulous malformations of the brain. The etiology of this outflow obstruction is unknown but may be related to underdevelopment of the jugular bulb, abnormal skull base maturation, and high-flow angiopathy of the venous system causing kinking or thrombosis at the tentorial or dural edge at the skull base. Because of this outflow restriction, the vein of Galen dilates and blood is refluxed into other, normal cerebral veins (internal cerebral, vermian, hippocampal, basal, medial ventricular, parietal, and occipital veins or other normal tributaries of the vein of Galen).

Fig. 69.1 A male patient presented with severe congestive heart failure (CHF) and acidosis at birth. His Apgar score was 5, with severe respiratory distress. The head circumference was 50 cm and the weight was 3.3 kg at birth. The patient was intubated and placed on dopamine and dobutamine drip as well as on furosemide. (a) A computed tomographic scan at 2 days old demonstrates a dilated midline vessel suggesting a vein of Galen aneurysmal malformation (VGAM) and mild hydrocephalus. Because of progression of the CHF, the patient underwent cerebral angiography and endovascular treatment at 4 days of age. Left vertebral artery injection in (b) anteroposterior (AP) and (c) lateral views demonstrates a choroidal-type VGAM draining to the median vein of the prosencephalon, then to the embryonic falx sinus. Multiple fistulas to the anterior portion of the median vein of the prosencephalon are supplied by bilateral posterior choroidal arteries and thalamoperforators. No straight sinus is seen. (d) After the left vertebral angiogram, the left posterior choroidal feeder was superselectively catheterized. Superselective angiogram shows a high-flow fistula. This was embolized with *N*-butyl-cyanoacrylate (NBCA) under systemic hypotension. (*continued*)

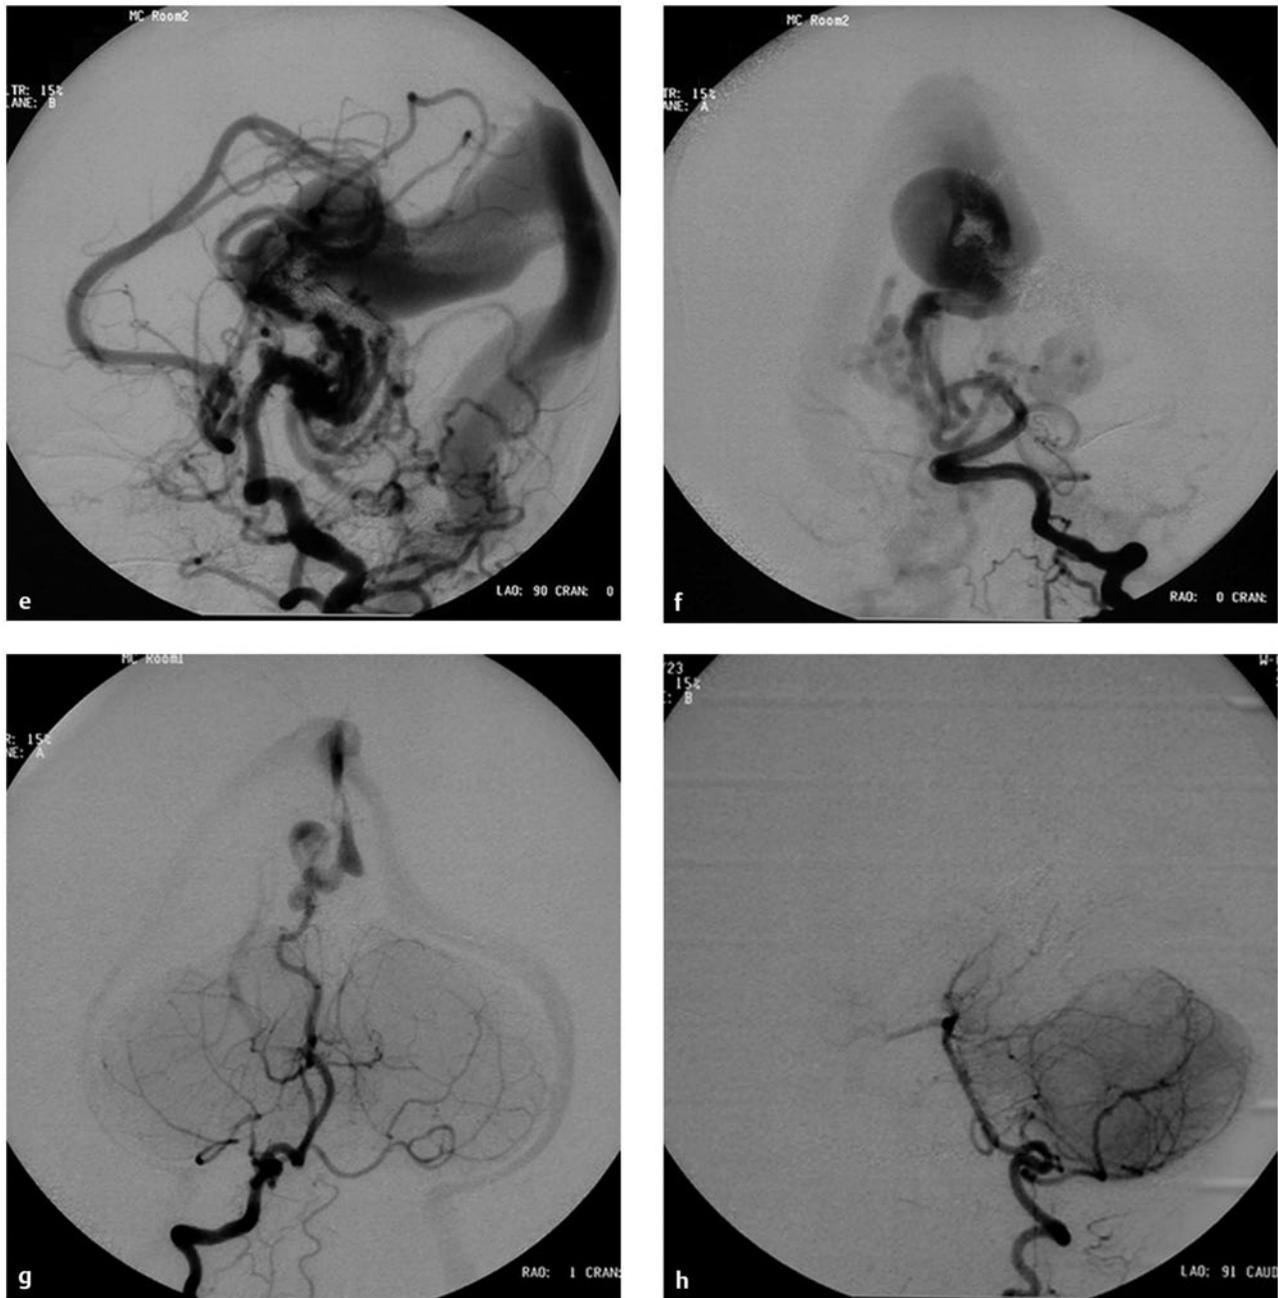

Fig. 69.1 (continued) (e) After embolization of the left common carotid artery, the lateral view demonstrates the remaining fistulas supplied by the posterior choroidal arteries and the left anterior cerebral artery. (f) After embolization of the left vertebral artery, angiogram demonstrates decreased but remaining fistulas. The patient underwent another embolization at 11 days old because of persistent CHF. At 11 months old, the patient underwent a third-stage embolization. At this time, the patient had no CHF but had moderate developmental delay with hypotonia. (g) Right vertebral artery angiogram in the AP view demonstrates a significant decrease in the size of the fistula and the median vein of the prosencephalon. The remaining fistula is supplied by the posterior thalamoperforator, which is increased in size compared with the previous angiogram [compare with (f)]. Complete occlusion of the VGAM was accomplished by the third embolization. (h) The right vertebral artery in the AP view demonstrates no opacification of the remaining fistulas. Distal posterior cerebral arteries are not opacified in this injection. (continued)

This type of VGAD usually presents in childhood or young adulthood with intracerebral hemorrhage, focal neurologic deficit, or seizures. The differentiation between a VGAM and a tectal AVM based only on angiography can sometimes be difficult, but demonstration of transmesence-

phalic feeders by magnetic resonance (MR) imaging confirms a tectal location and VGAD.⁷ For treatment, transvenous embolization is **contraindicated** in VGAD because it may produce extensive venous thrombosis in deep cerebral veins.

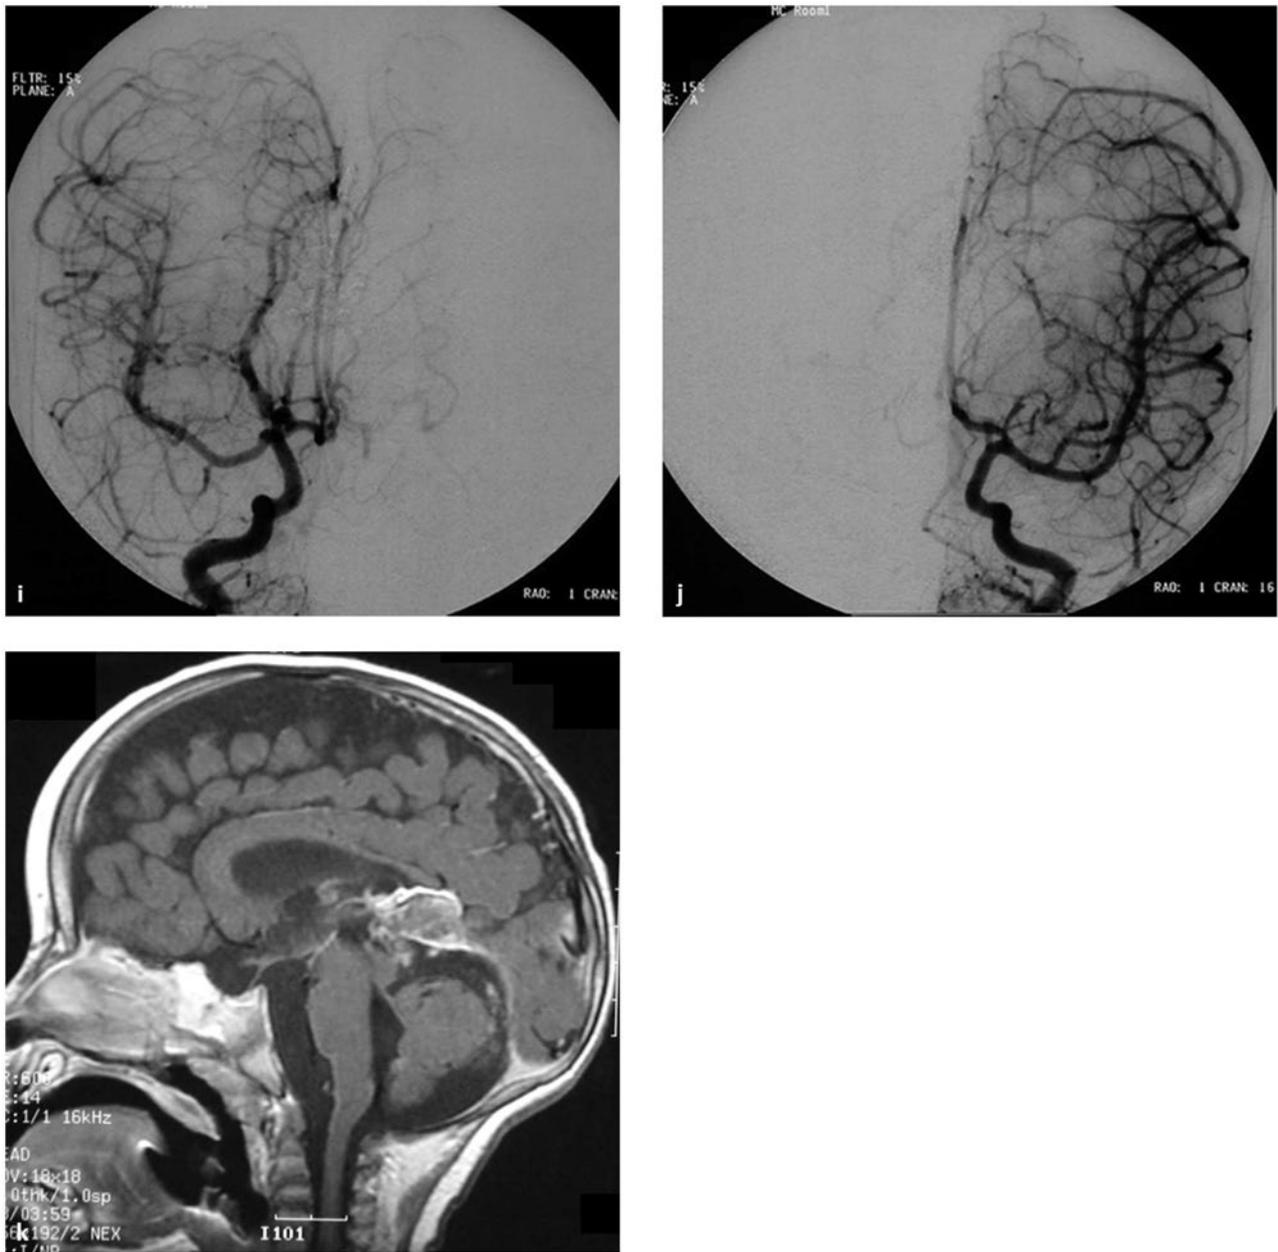

Fig. 69.1 (continued) (i) Right and (j) left common carotid artery angiograms in the AP view demonstrate no opacification of the fistulas. Distal posterior cerebral arteries were opacified through the posterior communicating artery bilaterally. The patient remained with moderate developmental delay. (k) T1-weighted sagittal magnetic resonance imaging with contrast 2 days after the third embolization demonstrates thrombosis and shrinkage of the median vein of the prosencephalon and the embryonic falcine sinus.

Dural Arteriovenous Malformation with Vein of Galen Aneurysmal Dilatation

Dural AVMs with VGAD are acquired lesions, usually presenting in the fourth or fifth decade of life, in which AV shunts are located in the wall of the vein of Galen itself. The dilatation of the vein of Galen is secondary to straight sinus stenosis or thrombosis. Reflux is always noted into afferent cerebral veins from the vein of Galen. The clinical presentation is similar to that of other dural AVMs draining into cerebral veins. Although the number of patients is small, the risk for progressive dementia in

this group is higher than in patients with other dural AVMs. The arterial supply of a dural AVM with VGAD is predominantly from dural falcotentorial arteries of the carotid or vertebral system and from the vasa vasorum to the wall of the vein of Galen, which arise from pial arteries.⁸

69.2.4 Vein of Galen Varix

VGV is dilatation of the vein of Galen without the presence of an AV shunt. Two types have been encountered in children. One is transient dilatation of the vein of Galen in neonates

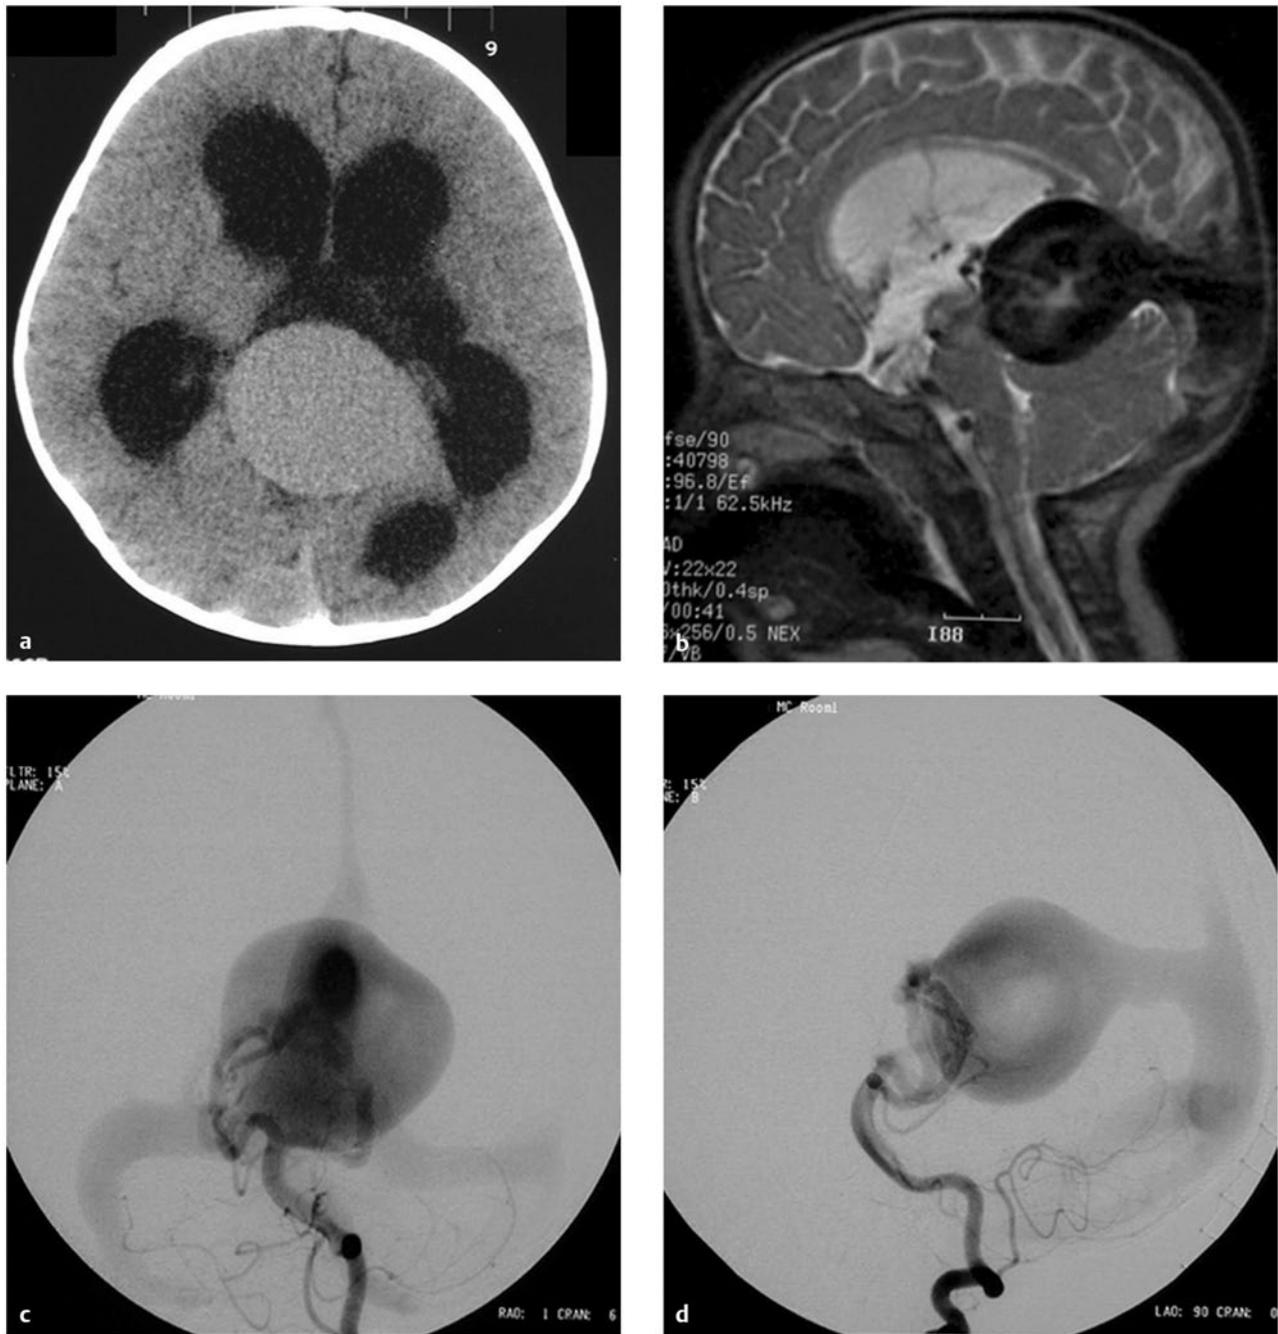

Fig. 69.2 A 6-month-old female patient presented with macrocephaly. The patient was developing normally. (a) Computed tomographic scan without contrast demonstrates hydrocephalus and a large midline vascular structure. (b) T2-weighted sagittal magnetic resonance (MR) image demonstrates a large midline vein draining to the embryonic falx and hydrocephalus. Left vertebral artery in the (c) anteroposterior (AP) and (d) lateral views demonstrates a mural-type vein of Galen aneurysmal malformation (VGAM) supplied by bilateral posterior choroidal arteries. The dilated median vein of the prosencephalon is draining to the embryonic falx with reflux to the superior sagittal sinus. (*continued*)

presenting with cardiac failure from a cause other than VGAM. This dilatation is usually noticed on an ultrasound study and disappears in several days following improvement of cardiac conditions. The dilatation itself does not cause symptoms. The second type of VGV occurs as an anatomical variation in which venous drainage of the brain converges toward the deep venous system. It is asymptomatic, but the lack of compliance of this

type of venous drainage may predispose to future venous thrombosis and resultant ischemic symptoms.

69.3 Clinical Presentation

Characteristic clinical manifestations of VGAM occur in each age group, neonatal and infant. In neonates, cardiac failure is

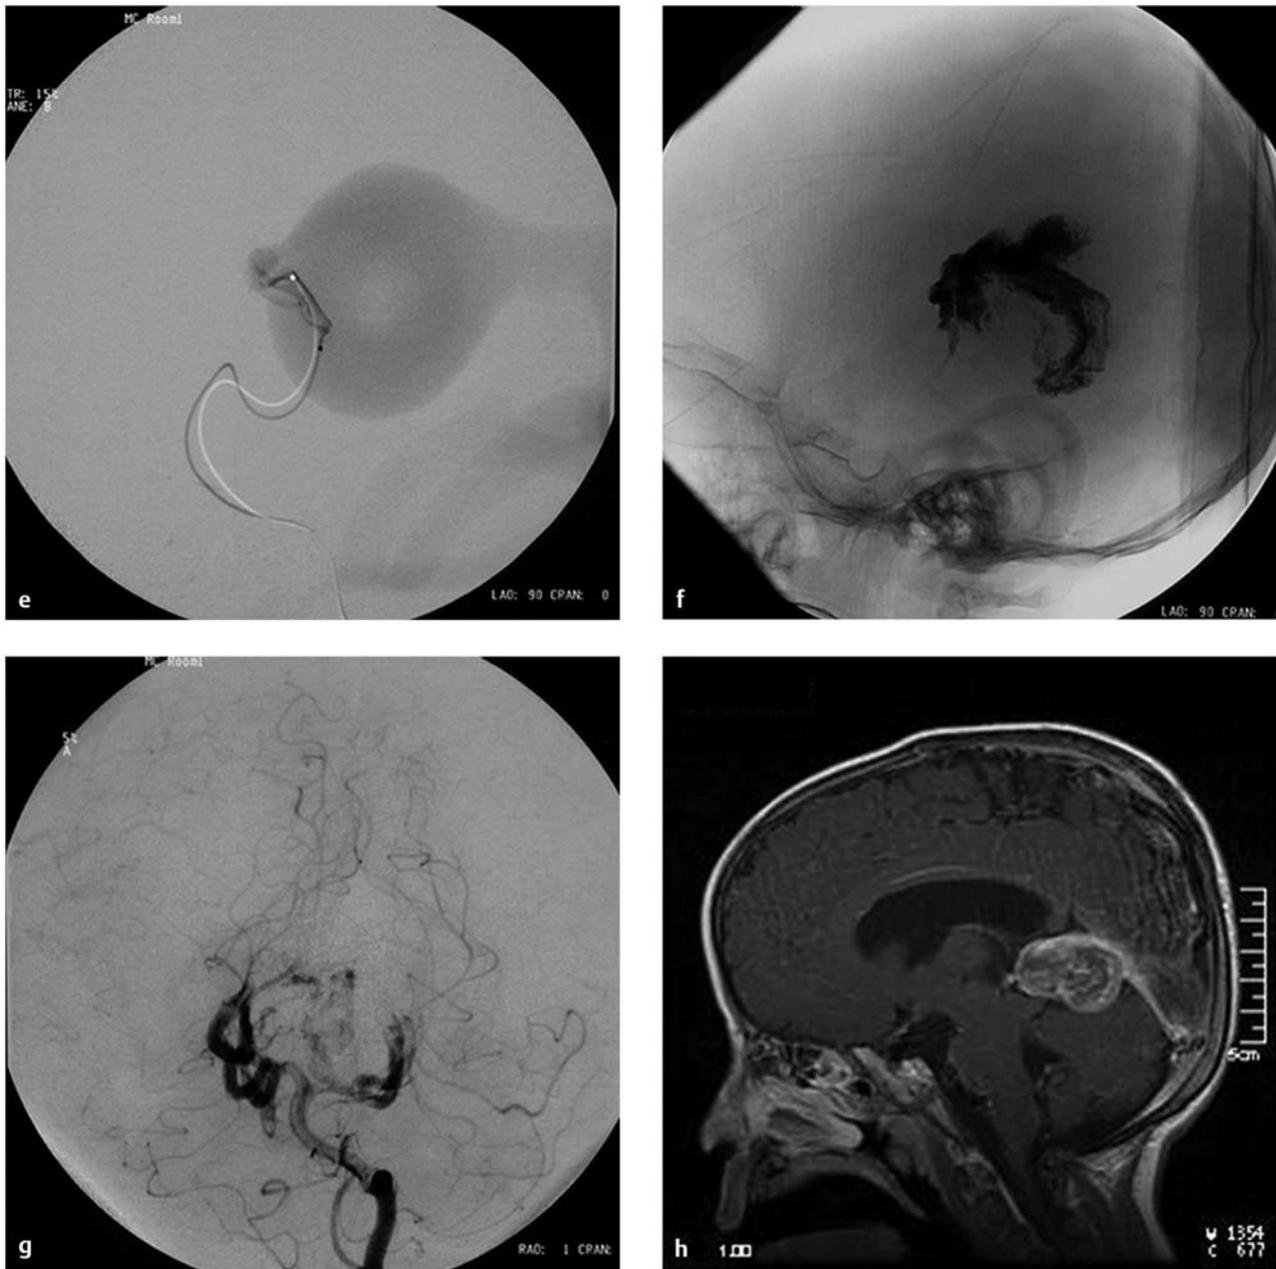

Fig. 69.2 (continued) (e) Superselective angiogram of the left posterior choroidal artery showing a high-flow fistula. This was embolized with *N*-butylcyanoacrylate (NBCA). (f) Lateral skull film showing the NBCA cast penetrating into the venous side. (g) Left vertebral angiogram in the AP view after one NBCA embolization demonstrating almost complete obliteration of the fistulas with minimal residual shunting, showing that this VGAM was a single-hole mural-type fistula. (h) T1-weighted sagittal MR image with contrast 5 months after the embolization demonstrating complete thrombosis and shrinkage of the dilated vein. The ventricular size also decreased without ventriculoperitoneal shunt. The patient remained neurologically normal with normal development.

usually the most prominent clinical feature, whereas in infants hydrodynamic macrocephaly and neurologic symptoms are more frequent.

69.3.1 Neonatal Cardiac Failure

In the neonate, cardiac failure is the most pressing symptom, ranging from asymptomatic cardiomegaly to multiple-organ failure. The reasons for this wide spectrum of cardiac manifestations

are still poorly understood. The size of the shunt, the type of venous drainage, the degree of outflow restriction, the complexity of the arterial supply to the VGAM, and the different responses of individual patients to cardiac stress are contributory. After a brief initial period of stabilization, in most cases the neonate's congestive heart failure (CHF) worsens during the first 3 to 5 days of life, then stabilizes and improves with appropriate medical management. Severe heart failure can cause neurologic dysfunction in newborns with VGAM. Cyanosis can be associated

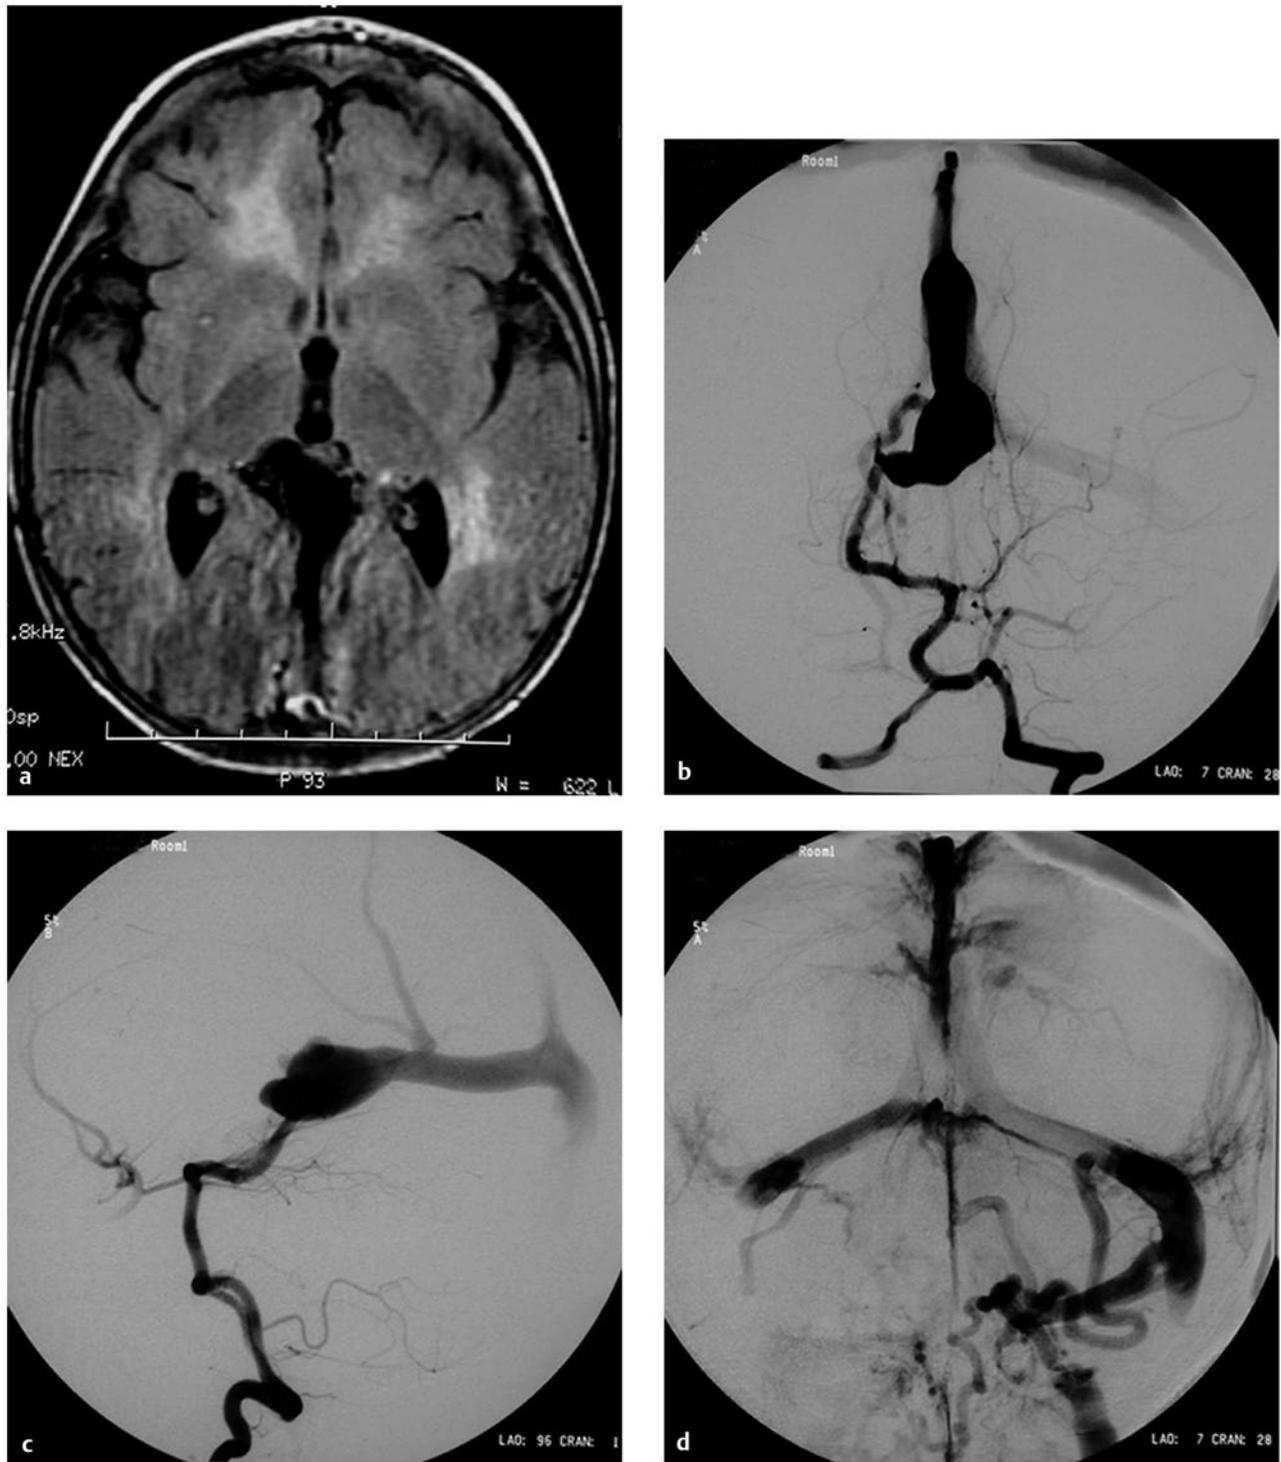

Fig. 69.3 A 12-month-old male patient presented with a 1-month history of seizures. (a) Magnetic resonance (MR) image demonstrates evidence of diffuse brain congestion and midline vascular malformation. The night before the angiography, the patient became obtunded with opisthotonic posturing. (b) Frontal and (c) lateral angiograms demonstrate an arteriovenous fistula from the right posterior choroidal artery to the dilated vein of Galen, which drains to the embryonic falcine sinus. There is reflux of venous drainage to the right basal vein of Rosenthal and the superior and inferior sagittal sinuses. (d) Late venous phase demonstrates significant venous stagnation and occlusion of both sigmoid sinuses with suboptimal collateral venous drainage. Acute venous hypertension due to sinus occlusion was thought to be the cause of acute deterioration. (*continued*)

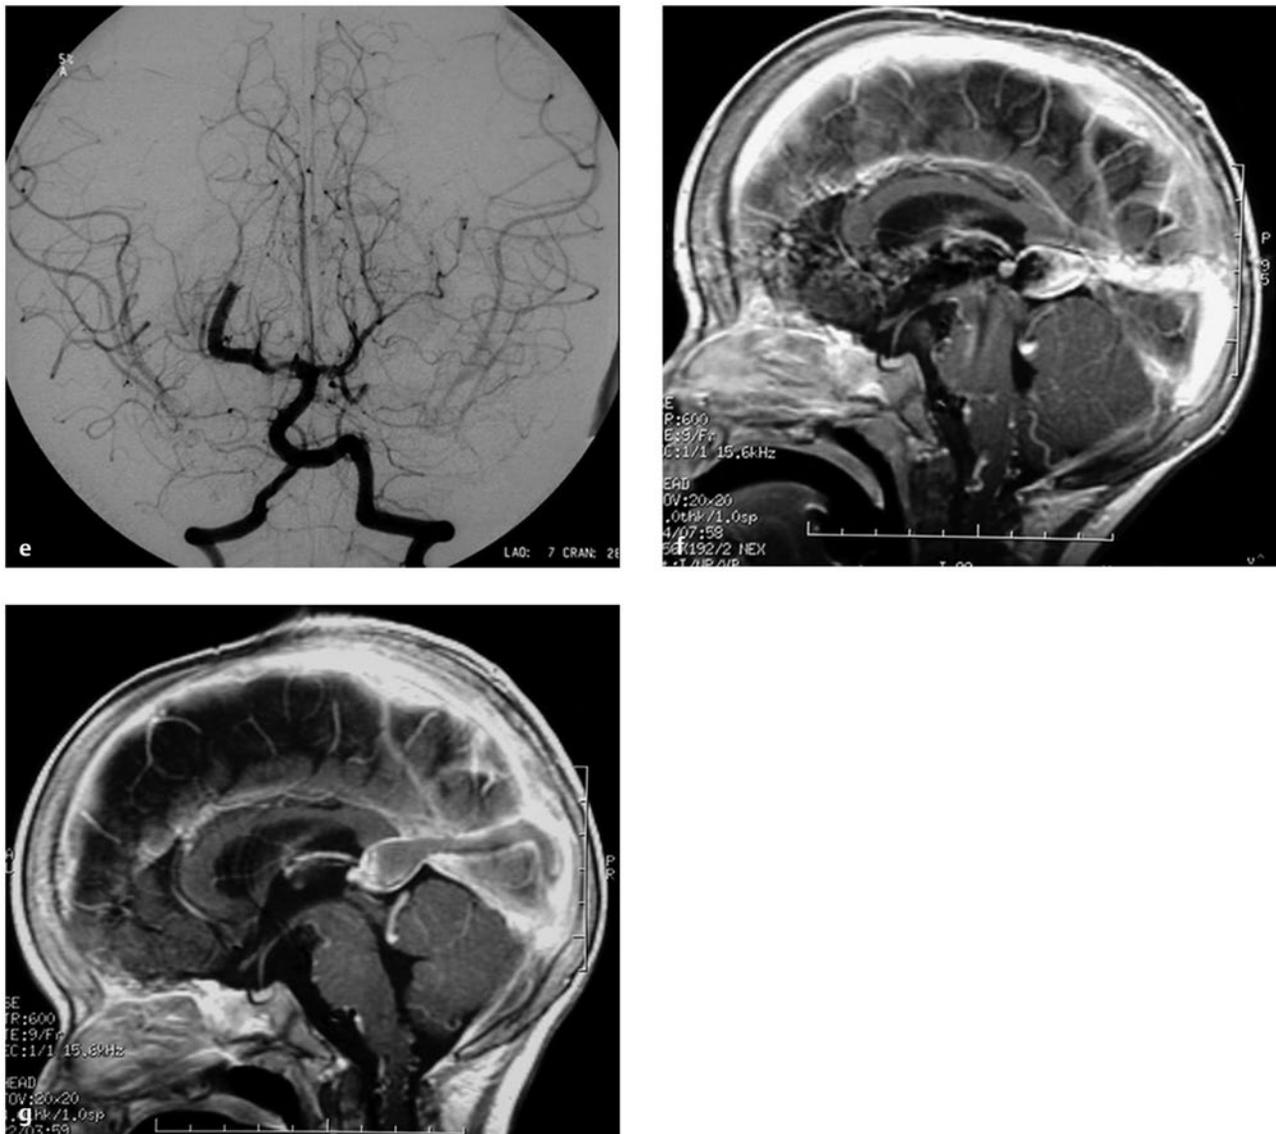

Fig. 69.3 (continued) (e) The patient underwent endovascular embolization with *N*-butyl-cyanoacrylate (NBCA), resulting in complete occlusion of the single-hole fistula. T1-weighted sagittal MR imaging with contrast (f) before and (g) after the embolization showing decreased congestion of the brain and thrombosis of the vein of Galen and embryonic falicine sinus. Note the increased cerebrospinal fluid space and decreased size of the veins in the posterior fossa after embolization. The patient was discharged neurologically intact without seizures.

with the heart failure because of a right-to-left shunt from a patent ductus arteriosus, from a patent foramen ovale, or from pulmonary hypertension that may be irreversible, even after treatment. A patent ductus arteriosus can worsen the clinical situation and may require cardiac surgery. Cardiac failure has been diagnosed prenatally in a few patients and is usually associated with major neonatal cerebral ischemia and encephalomalacia.

Cardiac manifestations have been reviewed for antenatally diagnosed VGAM.⁹ In the series of Rodesch et al⁹ of 18 patients with antenatally diagnosed VGAM, 17 were born with cardiac failure. During antenatal ultrasound examination, cardiac enlargement was noted in 4 of 17 patients. These 4 patients all had a low neonatal score because of systemic failure or because of encephalomalacia. Treatment was withheld in these 4 patients, and they soon died. The others were medically managed

and underwent embolization at between 2 and 13 months. Their neurologic outcome was reported to be excellent at 2-year follow-up. The antenatal diagnosis of VGAM is not an absolute indication for emergency embolization in the neonatal period. Macrocrania in uterus has no negative significance in our experience.

The pathophysiology of cardiac failure in neonates with high-flow AV fistulas starts with increased venous return and subsequent right-sided heart overload. The AV shunts therefore lead to right-sided heart dilatation, pulmonary arterial hypertension, and increased pulmonary blood flow. The resultant greater pulmonary venous return to the left side of the heart increases the left ventricular diastolic volume, which may be further increased by a patent ductus arteriosus if present. The increased left ventricular preload results in increased

myocardial oxygen requirements. Coronary perfusion to the left ventricle occurs mainly during diastole and depends on the systemic arterial–intramyocardial diastolic pressure difference as well as the duration of diastole. Therefore, a reduction in arterial diastolic pressure (as observed in an AV shunt), an increase in end-diastolic pressure (due to increased preload), and a reduction in the diastolic period (tachycardia) are all detrimental to myocardial perfusion and hence oxygen delivery, which precipitates left ventricular failure. Thus, even if only the right ventricle fails initially, biventricular failure frequently follows depending on the size of the left-to-right shunt.

The neonatal heart is limited in its reserve capabilities and cannot cope with the extra work imposed by the fistula. These factors explain the rapid progression toward cardiogenic shock observed in neonates with high-flow fistulas. Furthermore, the transition from a fetal circulatory pattern to an adult circulatory pattern is complex, and both the pulmonary circulation and the systemic circulation remain highly unstable during the first week after birth. This can explain a persistent transitional circulation with shunts through a patent ductus arteriosus and a foramen ovale and pulmonary hypertension, which both worsen the systolic and diastolic wall stress.

Hepatomegaly with hepatic dysfunction, prerenal azotemia followed by oliguria, and metabolic and lactic acidosis are also present in severe cardiac failure and are negative predictive factors.

At present, in utero diagnosis has become more frequent, and we have developed a multidisciplinary strategy to optimize the care of these challenging patients. After the diagnosis is made, usually by prenatal ultrasound, we obtain MR imaging in utero to confirm the diagnosis and search for any obvious brain damage. The mother then undergoes an evaluation by a pediatric cardiologist, which includes fetal ultrasound and echocardiography. Fetal echocardiography is performed when a VGAM is diagnosed prenatally primarily to assess the fetal heart size and determine the presence of associated heart defects. The fetal heart size is assessed by measuring the cross-sectional area of the fetal heart in a four-chamber view and the cross-sectional area of the fetal chest. Normally, the cross-sectional area of the fetal heart is one-third of the cross-sectional area of the chest. This ratio may be increased to more than one-half in a fetus with VGAM. When the ratio of the cross-sectional area of the fetal heart to the cross-sectional area of the chest is 0.5 or more, the mother is started on digoxin. This is given under cardiac monitoring at doses of 0.5 mg intravenously every 6 hours until a maternal serum digoxin level of close to 2 ng/dL is reached. At that point, the patient is switched to an oral maintenance dose of digoxin, usually about 0.5 mg twice daily, and a digoxin level of approximately 2 ng/dL is maintained until delivery.

Neonatal Care

When possible, the patient is born at our hospital and transferred to the neonatal intensive care unit for immediate evaluation by the pediatric cardiologist and intensivist. The opportunity is taken to obtain umbilical arterial and venous access, which is critical. If needed, respiratory support with positive-pressure ventilation or intubation is initiated. A cardiovascular examination, echocardiography, and transcranial ultrasound are obtained on day 1 of life. Heart failure, when present, is

managed with medications. If the patient cannot be weaned from ventilator support or intravenous medications or is progressing toward multiple-organ failure, then endovascular intervention to close as much of the fistula as possible and control the heart failure is considered. Otherwise, a stable patient is followed with a plan for treatment in 5 to 6 months. As our experience with newborns increases, our threshold for intervention has been lowered toward earlier intervention, which avoids the need to deal with a very sick newborn who has a greater likelihood of irreversible damage. We have found certain early echocardiographic findings to be prognostic indicators of the necessity of early intervention. In addition to generalized cardiomegaly and hypercontractility, these echocardiographic findings include pulmonary hypertension, frequently with suprasystemic pressure in the pulmonary artery as measured by tricuspid insufficiency velocity. There is persistent fetal circulation, with right-to-left shunting at the level of the patent ductus arteriosus and the patent foramen ovale. Almost all patients requiring neonatal intervention have dilatation of the ascending aorta and the carotid arteries, with Doppler findings of severe diastolic reversal of flow in the descending aorta. Patients with severe heart failure and pulmonary hypertension are maintained on mechanical ventilation, at times with the use of nitric oxide. They are started on intravenous inotropic agents, such as dopamine, dobutamine, and milrinone, as well as furosemide and digoxin. All patients undergo neuroimaging with MR imaging techniques, including diffusion-weighted imaging, MR angiography, and MR venography, before intervention. Neuroimaging assesses the brain parenchyma for underlying permanent damage or ischemic changes and delineates the vascular anatomy and venous outflow. High flow through the sinuses, without outflow restriction, also correlates with uncontrolled heart failure and the need for early intervention. Evidence of parenchymal damage is used for the prognosis and in the decision to proceed with or withhold treatment.

With the present availability of noninvasive imaging, there is no role for diagnostic angiography; the only reason to undertake invasive intervention is for emergent treatment, and this should be done in very specialized centers. All patients are treated with transarterial *N*-butyl-cyanoacrylate (NBCA) liquid embolic material, which is used to target the fistula sites of the malformation. Although in the past we have used transumbilical access to the cerebral circulation,²⁴ at present we routinely use ultrasound-guided percutaneous femoral artery access. Transvenous access is used in older children who have no femoral access or the residual arterial supply is collaterals, distal perforators secondary to proximal pedicle occlusion versus fistula closure. In neonates, the venous approach was not necessary in any cases. The goal of embolization in the neonate is to reduce AV shunting to permit control of the CHF.

Endovascular Treatment

The treatment of a newborn in heart failure must be very efficient, with the extremely limited use of liquids and contrast material, which may be restricted by the patient's weight (up to 10 mL/kg). If the treatment goal cannot be achieved in one session, the patient will undergo a second session of treatment another day. After the resolution of severe heart failure, patients return for further treatment sessions at approximately 6 to 8

months of age or earlier, if necessary. The final goal is complete obliteration of AV shunting without neurologic injury.

In 2012, we reported our results of the management of 16 patients who presented to the INN during the antenatal or neonatal period with a diagnosis of VGAM. Of 16 patients, 10 had an antenatal diagnosis of VGAM by prenatal ultrasound in the third trimester. VGAM was diagnosed in the remaining 6 patients after birth. Of the 16 patients, 7 responded to medical management in the neonatal intensive care unit, were discharged from the hospital, and returned for endovascular treatment at a later date. Nine patients required endovascular intervention because of refractory heart failure within the neonatal period. All 9 patients had a choroidal-type VGAM and required treatment within the first 10 days of life. Associated fetal cardiac defects were seen in 4 patients, who had sinus venosus, atrial septal defect, or a mild aortic coarctation (1 patient). Of 8 patients, 5 required more than one endovascular treatment session during the neonatal period to adequately control heart failure. Control of heart failure was achieved in 8 of 9 patients. One premature baby who weighed 1.5 kg died after treatment because of diffuse intracranial hemorrhage. One technical complication occurred, in which a microcatheter rupture resulted in stroke and a permanent neurologic deficit of mild hemiparesis. After endovascular embolization, routine cross-sectional imaging demonstrated that 3 patients had asymptomatic intracranial hemorrhage. These included 2 patients in the series who were treated despite parenchymal abnormality on pretreatment MR imaging. In these patients, asymptomatic petechial hemorrhagic conversion occurred in the preexisting area of diffusion abnormality. After embolization, 8 of 9 patients were managed medically and discharged from the hospital on oral medications.

Long-term Outcomes

Of the 8 patients who survived the neonatal period, angiographic obliteration has been documented in 6 at an average age of 20 months after an average of 4.2 treatments (► Fig. 69.1). The remaining 2 patients have an estimated 95% closure of the AV shunting with a significant reduction in the size of the vein of Galen. Clinical outcomes are as follows: One premature baby died. Two of the 8 patients have minor neurologic deficits. In one, a microcatheter rupture resulted in an intraprocedural left middle cerebral artery stroke during his second treatment. He has a mild left hemiparesis and undergoes physical therapy. The other patient had focal posterior cerebral artery territory infarcts on pretreatment MR imaging because of hypotension in the neonatal period and has mild motor and language delay. One of the 8 patients has severe developmental delay and seizures. This patient had bilateral laminar necrosis on pretreatment MR imaging. Five of the 8 surviving patients have normal neurologic development and are achieving normal developmental milestones. In our series, one patient developed chronic occlusions of the femoral arteries with the formation of collaterals seen on angiography. There were no clinical sequelae. There are also technical considerations in the embolization of these lesions. The usefulness of the transvenous approach in neonates has been reported, given the difficulty with transarterial access.^{17,29} In true VGAM, the transvenous approach may be a viable option. However, it has been our experience that a vein of Galen malformation cannot be distinguished from a vein of

Galen dilatation with normal cerebral veins draining into the aneurysm with certainty in a neonate. A transvenous occlusion of the aneurysm in a patient with a vein of Galen dilatation can have devastating consequences, such as postprocedure venous infarct and hemorrhage, by obliterating the venous outflow of the normal brain. A recent literature review of VGAM treatment supports this, with patients treated transarterially exhibiting a higher rate of “good” clinical outcome.³⁴ Although in the past we reported the use of a transumbilical approach in neonates with VGAM,²⁴ since the initiation of the use of ultrasound for femoral artery cannulation, we have had no failures with this approach. A unique complication of femoral artery occlusion due to repeated femoral artery access occurs in pediatric patients in comparison with adults. After the procedure, careful compression and hemostasis are essential because the long-term patency of the vessels may become compromised. With advancements in our treatment strategy over the past two decades, as discussed above, our mortality rate has dropped to 11% in this current series. Normal neurologic outcome has been achieved in 66.7% of patients and mild delay in 11%, with a good outcome rate of 77.8%.¹⁰ The importance of an interdisciplinary team starts at the very time of diagnosis. In utero management by an experienced high-risk obstetric team and pediatric cardiologist is essential. Fetal and neonatal echocardiography can identify patients in whom refractory heart failure is likely to develop. At present, because of significant advances in endovascular techniques, it is possible to intervene much earlier, before end-organ damage occurs.

69.3.2 Infant Hydrodynamic Disorder

In infants, the presenting symptoms are usually caused by hydrodynamic disorders. Hydrodynamic disorders, however, can manifest in fetuses, neonates, and infants. They manifest as macrocrania, which results from enlargement of the cerebrospinal fluid space, hydrocephalus, and increased intracranial pressure and can be associated with developmental delay and mental retardation. Decompensation can occur when cranial sutures close. The drainage of the AV shunt increases the pressure in the torcular and superior sagittal sinus, thereby creating a hemodynamic obstacle to the cortical and deep venous drainage of the brain. This condition is aggravated by the fact that the venous drainage of the brain converges to the torcular at this age. Further compromising the cerebrospinal fluid drainage, the pacchionian granules do not mature until infancy. Distal venous stenosis or secondary venous occlusion can occur and further compromise the cerebral venous drainage. The direction of flow in the cerebral veins is usually reversed and rerouted toward the cavernous sinus and ophthalmic veins, causing dilatation of the facial veins or epistaxis, or to the basisphenoid sinus and pterygoid veins. If these alternative pathways of venous drainage are not yet well developed, cerebral venous congestion can lead to brain edema, hypoxia, and hydrocephalus, aggravating neurologic conditions.¹¹ If the sylvian veins and the cavernous sinus develop with adequate extracranial outflow, spontaneous stabilization of the hydrodynamic disorder can occur.

Hydrocephalus results from the impairment of cerebrospinal fluid resorption due to venous hypertension. Although the VGAM may compress the aqueduct of Sylvius, obstructive hydrocephalus is rare. Ventricular shunting interferes with the water balance between the extracellular and intravascular compartments and

may cause brain edema, enlargement of the VGAM, seizures, subdural hematoma, and overshunting with slit ventricles.

69.4 Natural History

69.4.1 Cerebral Calcification

Cerebral calcifications are typically bilateral, symmetric, and located in the transcerebral venous watershed area between the superficial and deep venous system. When present, cerebral calcifications are objective anatomical evidence of a venous hypoxic disorder and its hydrodynamic consequences. Calcification is often associated with subependymal brain atrophy and may secondarily produce seizures.

69.4.2 Dural Sinus Occlusion and Venous Hypertension

Progressive dural sinus occlusion is common in the evolution of VGAM, but its cause is unknown. This phenomenon is not specific to VGAM but is frequently seen in high-flow fistulas in young children. We are not aware of any experimental studies that have investigated the etiology of progressive sinus occlusion. We speculate that this is related to a combination of underdevelopment of the jugular bulb, abnormal skull base maturation due to macrocrania, and high-flow angiopathy of the venous system due to high-flow fistulas that may lead to kinking or thrombosis at the tentorial or dural edge at the skull base. The symptoms depend on the timing between sinus occlusion and capture of the sylvian veins by the cavernous sinus and on the patency of the jugular bulbs and veins. When the jugular bulbs are occluded, the veins of the foramen ovale or the ophthalmic veins will drain the cavernous sinus, which may cause dilatation of the facial veins. If both the VGAM and the brain drain into the same cavernous sinus, facial vein dilatation will be more prominent and epistaxis can occur because of nasal vein congestion. If collateral venous outlets are insufficient, cerebral pial venous congestion may develop. The long-term result of pial venous congestion is chronic cerebral ischemia, manifested by development of calcifications and the peculiar appearance of the chronically congested cortical veins. If further outflow restriction of the venous drainage of the VGAM occurs, pial cortical venous reflux will develop, which can cause acute focal neurologic deficits, seizures, and hemorrhages. When these occur, they represent rare examples of hemorrhages seen in children or young adults with true VGAM.

Prolapse of the cerebellar tonsils is a manifestation of infratentorial pial venous congestion due to sinus occlusion. If the prolapse has not been present for a long time, it may disappear with occlusion of the AV shunts. Prolapse of the cerebellar tonsils usually does not cause any specific symptoms at this age. The prolapse is not related to a global increase in intracranial pressure and is not an indication for emergency ventricular shunting, but rather for endovascular embolization to decrease venous hypertension.

69.4.3 Hemorrhage

Intracranial hemorrhage is rare but possible in patients with VGAM. Intracranial hemorrhage can occur if venous stenosis or

occlusion reroutes the venous drainage of the AV shunt into pial veins. This usually occurs in older children and young adults as a secondary manifestation. We have not encountered hemorrhage as the initial presentation in true VGAM. In contrast, hemorrhage is a frequent manifestation of VGAD. Most cases of so-called vein of Galen malformation presenting with hemorrhage in the literature are actually VGAD, not true VGAM. VGAM can also bleed after partial treatment with venous outflow occlusion, which is more common after transvenous than transarterial embolization. Other types of bleeding, such as hemorrhagic infarction, intraventricular hemorrhage, and subdural hematoma, may occur following ventricular shunting or transvenous embolization.

69.5 Treatment

Depending on the patient's age and the type, onset, and predominant symptoms of VGAM, the objectives of treatment will vary. A major breakthrough in treatment began in the early 1980s with endovascular embolization in the management of VGAMs.¹²⁻¹⁶ Before the introduction of endovascular embolization for the treatment of VGAM, surgery had been performed with uniformly poor results.¹⁷ Mickle and Quisling¹⁸ introduced the neurosurgical transthoracic venous approach to control severe CHF in 1986, and Lasjaunias et al reported the first complete transarterial occlusion and cure in 1989.¹⁹⁻²¹ If treatment is properly timed and performed by a group well trained in pediatric interventional neuroradiology and endovascular neurosurgery, embolization of VGAM is the present treatment of choice and can lead to good clinical outcomes. Medical, surgical, and/or radiosurgical treatment is also used, either alone or combined with endovascular therapy. The indication for radiosurgery is limited to the last stage of treatment for a small residual in older children.

69.5.1 Indications and Goal

The ultimate goal of treatment for VGAM is complete obliteration of the lesion leading to normal development of the patient without neurologic deficits. The immediate treatment goal, however, is different and depends on the age of the patient. The primary goal of treatment in neonates is obliteration of the major portion of the fistulas to allow the resolution of CHF. The combination of neonatal macrocephaly or moderate hydrocephalus with CHF that is not life-threatening does not mandate urgent treatment. Conversely, if significant brain damage is demonstrated by computed tomography (CT), ultrasound, or MR imaging, treatment is not indicated because the clinical outcome is poor even if the lesion is anatomically cured (► Fig. 69.4).²²⁻²⁴ The extent of angiographic evaluation before treatment should be limited in neonates because they usually have compromised cardiac and renal function and cannot tolerate a significant volume and contrast medium load. Immediate complete occlusion of the malformation is not always possible, but it is usually not necessary in neonates to achieve the immediate goal.

For infants and children, the immediate goal is to restore the normal hydrovenous equilibrium to permit normal development and at the same time to obliterate the lesion. Our special interest in patients at this age is to avoid ventricular shunting

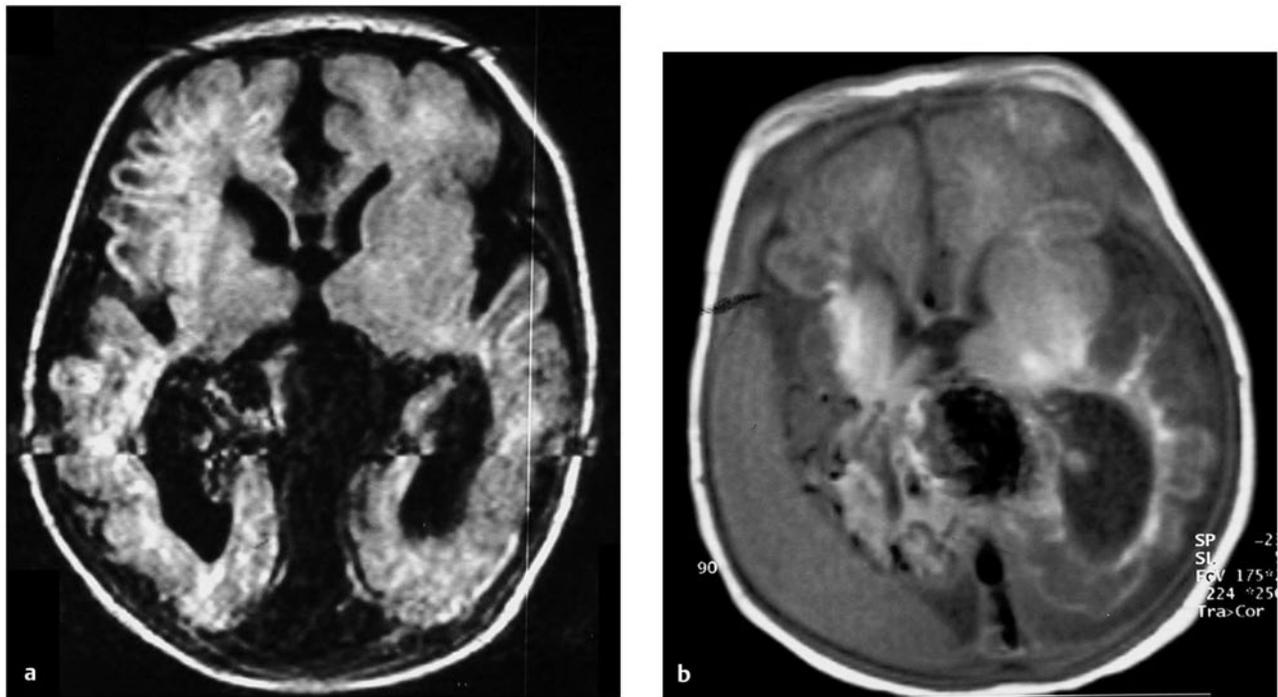

Fig. 69.4 This male patient presented with severe congestive heart failure (CHF) at birth. (a) FLAIR (fluid-attenuated inversion recovery) magnetic resonance (MR) imaging at 1 day old demonstrates severe brain tissue loss and midline vascular malformation with a dilated vein of Galen. The patient underwent transarterial and transvenous embolization at 2 days and at 12 days old at an outside institution with technical success in partial obliteration of the vein of Galen aneurysmal malformation, although treatment was not indicated because of significant brain damage. (b) T1-weighted MR imaging at 25 days old demonstrates the progression of brain atrophy and a subdural fluid collection. *Arrow* indicates coils in the draining vein. At 18-month follow-up, the patient had no CHF but was on tracheostomy and tube feeding with spastic quadriplegia. The patient underwent embolization at this time with complete occlusion of the malformation and relief of apparent headaches.

by performing timely endovascular treatment. Therefore, if the head circumference increases rapidly, or if there is MR imaging evidence of increased intracranial pressure, or if the clinical follow-up demonstrates a significant developmental delay, then urgent embolization should be performed. In our experience, transarterial embolization is effective in decreasing the venous pressure and relieving the clinical symptoms of the hydrodynamic disorder. However, embolization should be performed before the full development of hydrocephalus and its clinical symptoms, even if the VGAM fistulas cannot be completely occluded. If endovascular treatment is performed after the full development of hydrocephalus, the effect of embolization is usually insufficient, and a ventricular shunt should then be considered. Of note, if further endovascular treatment is considered, embolization should not be performed for at least a few days after the placement of a ventricular shunt to avoid the risk for upward cerebellar herniation secondary to a rapid decrease in the supratentorial pressure.

If cerebral pial venous congestion develops and leads to acute focal neurologic deficits, seizures, and hemorrhage, emergency endovascular treatment should be performed to reduce cerebral venous hypertension. The results of embolization should be rapidly detectable clinically and recognizable by the progressive disappearance of the facial venous collateral circulation

and neurologic improvement. Dural AV shunts may develop within thrombosed portions of the sinus. They usually disappear following complete obliteration of the VGAM.

For patients who were referred late for treatment with already impaired neurologic function or severe mental retardation, we still perform endovascular treatment to improve their quality of life and can usually achieve satisfactory results, even though the lesion is not completely occluded. A determination of the end point of the treatment is based mainly on the draining pattern of the brain and the malformation, which is related to the degree of development of the cavernous sinus, maturation and patency of the jugular bulb and internal jugular veins, and patency and functional efficacy of the embryonic sinuses.

In summary, indications for early intervention include the following: (1) unstable or progressive cardiac failure despite adequate medical treatment, (2) the recognition of developmental delay or venous ischemic changes, such as calcifications, (3) the development of significant macrocrania, and (4) pial venous hypertension. During conservative follow-up, monthly measurement of the head circumference and weight and 3-month follow-up MR imaging should be obtained. If MR imaging shows any sign of the development of hydrocephalus or ischemic changes in the brain parenchyma, endovascular treatment should be performed without delay.

69.5.2 Evaluation

The evaluation of a VGAM should include the following: (1) clinical history and physical examination, (2) assessment of renal and liver function, (3) transfontanel ultrasound to evaluate the size of the ventricles and brain parenchyma, (4) cardiac ultrasound to assess cardiac function and to evaluate associated cardiac malformation, and (5) MR imaging of the brain to obtain morphological information regarding the lesion and the brain parenchyma. Angiography in the neonatal period should be obtained only when embolization is considered at the same setting. In view of the limited arterial access, diagnostic angiography alone is not indicated. The weight and head circumference of the patient should also be carefully followed before and after treatment.

The indication for, and timing of, treatment should be decided based on a careful assessment of the neurologic symptoms, growth and development, cardiac and other systemic manifestations, and imaging studies of the VGAM and brain parenchyma. If the patient is clinically stable with or without cardiac medication, it is preferable to delay the treatment until 5 to 6 months of age.

69.5.3 Endovascular Treatment

The endovascular treatment of VGAM is performed either by occluding the fistula sites via a transarterial approach or by occluding the ectatic vein via a transvenous approach. Transfemoral transarterial embolization is our first treatment choice. A transumbilical artery approach is possible for newborn patients and sometimes preferable because of the small size of the femoral artery.²⁵ The risk for immediate or delayed hemorrhagic complications is significantly less with transarterial embolization. To achieve satisfactory results, proper patient selection is mandatory. If the venous route is under consideration, one must be absolutely certain that the dilated vein is not connected to normal cerebral veins.

A 4F sheath is used for transfemoral access. Pretherapeutic angiography is performed with a 4F catheter and a low-osmolality and nonionic contrast material. The left or right vertebral artery injection in the frontal projection is usually the best first study to identify the largest fistula, which should be the first target for embolization. In neonates and infants, angiographic study before treatment should be limited because of the small body weight. Most neonates can tolerate 4 to 8 mL of contrast material per kilogram of body weight well. The total amount of contrast material that a patient can tolerate varies depending on the duration of the entire procedure and on urinary output. In older patients, full angiography can be performed before the treatment.

Following diagnostic angiography, transarterial embolization is performed with a flow-guided microcatheter placed through the 4F guiding catheter. Our first choice of embolic agent for transarterial embolization is NBCA. It is important to occlude the fistula site itself to avoid collateralization to the fistula. Complete closure of the malformation can be accomplished in one session, particularly in patients with a mural-type VGAM. We have not experienced perfusion pressure breakthrough phenomena in our series. Following total or nearly total occlusion of the fistulas, progressive thrombosis and shrinkage of the

ectatic vein are observed on CT or MR imaging over several weeks. In patients with a more complex arterial supply, especially those with choroidal VGAMs, embolization should be staged. The clinical symptoms usually improve even after partial embolization.

Transvenous embolization of a VGAM may be accomplished by either a percutaneous transfemoral or a transtorcular approach. The transtorcular treatment can be performed by either surgical exposure of the torcular or ultrasound-guided percutaneous penetration of the overlying dura with a needle.²⁶ Reduction of AV shunting is achieved by packing the venous pouch with a variety of materials, including coils,^{26,27} nylon,²⁷ and balloons.²⁶ Several sessions of treatment may be required to achieve a satisfactory response.^{18,28,29} The extent of the embolization may be monitored during the procedure by the injection of contrast transarterially or directly into the pouch, or alternatively by the measurement of intra-aneurysmal pressure.³⁰ One may also consider angioplasty and stenting of the dural sinus for progressive sigmoid/jugular occlusion and severe intracranial venous hypertension when endovascular embolization does not improve the symptoms. The long-term durability of dural sinus stenting is unknown.

The venous approach is technically easier but in our experience leads to less favorable clinical outcomes compared with transarterial embolization. Long-term neurologic outcome after venous embolization is less clear, and venous embolization is contraindicated in VGAD associated with a pial AVM.³¹ It is not always easy to differentiate between a VGAM and a VGAD with a fistulous pial AVM. Even with a true VGAM, sudden complete occlusion of the draining vein may cause venous infarction or hemorrhage. A combination of transarterial and transvenous embolization may be beneficial for certain cases in which complete occlusion of the fistulas cannot be achieved by the transarterial approach alone. In such cases, transvenous embolization is performed at the end to close the small residual fistulas and completely obliterate the malformation.

69.5.4 Medical Treatment

The most important medical treatment in cases of VGAM is for cardiac failure in the newborn. If cardiac failure can be controlled with medical treatment, endovascular treatment should be delayed until the patient is 5 to 6 months old, when endovascular treatment is much easier and safer and carries less risk for ischemia of the leg following a transfemoral approach compared with the newborn period. The management of cardiac failure consists mainly of diuretics, pressors, and oxygenation with or without assisted ventilation, depending on the severity of the symptoms. Cardiac output can be improved by increasing cardiac contractility with inotropic agents. The effect of digitalis in the hyperkinetic state due to AV fistulas remains controversial, although it is, in general, the main agent used to increase myocardial contractility. There is no clear evidence that the use of digitalis to further increase the contractility of already hyperfunctioning myocardium has any clinical benefit. In situations of severely compromised cardiac output, dobutamine and dopamine can be used to augment myocardial contractility. If a patient does not respond to maximal medical treatment, emergency embolization of the VGAM is indicated. The cardiac status

effectiveness is uncertain for high-flow fistulas of VGAM. The latency period is prohibitive in achieving the occlusion needed for the normal developing brain. Stereotactic radiotherapy may be useful in an older patient who has relatively slow-flow residual shunts after endovascular treatment.

69.5.7 Outcome

A review of the literature shows that the outcome of both conservative management and surgical treatment has been poor, particularly for newborns and infants. In the review of 245 cases of Johnston et al,¹⁷ overall mortality was 91.4% in the neonatal group, with the majority of patients dying within 1 week of diagnosis or treatment. Mortality was 100% (12 patients) without treatment, 95% (38/40) with medical treatment, and 82% (14/17) with surgical treatment. In patients 1 to 12 months of age, overall mortality was 48%, and 50% of the survivors were neurologically impaired. Mortality was 73% (8/11) without treatment, 33% (2/6) with treatment only for CHF, 64% (7/11) with shunt placement only, and 32% (13/41) with direct operation. These cases most likely include a significant number of pial AVMs with VGAD, which are poor surgical candidates, and more mural-type VGAMs than choroidal-type VGAMs.

In the review of cases involving children 1 to 5 years of age of Johnston et al, the overall mortality was 42% (13/31), 67% (4/6) without treatment, and 35% (6/17) with direct surgery. Again, the cases likely include a significant number of pial AVMs with VGAD, especially in the group with no treatment.

Many survivors of any modality of treatment had significant neurologic deficits in all age groups.

Spontaneous thrombosis of the venous pouch and/or its outlets has been rarely reported (► Fig. 69.5).³⁴ It appears to occur more frequently in mural-type than in choroidal-type VGAM. It may be associated with increased intracranial pressure and/or venous ischemic episodes.

69.5.8 Neurologic Outcome after Embolization

In our surviving group of patients, 74% are neurologically normal. Among 193 patients, 20 (10.8%) have a severe neurologic or cognitive handicap. Some of them were in an irreversible state when they were referred to our center, but for the other patients a poor outcome was not anticipated.³⁵

69.6 Conclusion

An improved understanding of the clinical, anatomical, and pathophysiologic features of VGAM and the advent of endovascular embolization as primary therapy have significantly improved the formerly poor prognosis of VGAM. The majority of children can now survive with normal neurologic development after proper endovascular treatment. There is now no indication for VGAM surgery as the primary treatment modality. In addition, ventricular shunting can be avoided with timely embolization.

Pearls

- Diseases that cause enlargement of the vein of Galen include VGAM (enlargement of the median vein of the prosencephalon); VGAD (transvenous embolization is contraindicated), consisting of pial AVMs or dural AV fistulas; and VGV.
- The differentiation between a VGAM and a VGAD-associated pial AV fistula is based on the presence of venous reflux to normal veins and transmesencephalic feeders, and on the location of fistulas.
- There are two types of VGAM, choroidal and mural. Choroidal VGAMs are characterized by multiple high-flow fistulas, are present in neonates with severe heart failure, and are more difficult to treat. Mural VGAMs are characterized by one or a few fistulas, present in infancy as a hydrodynamic disorder, and are easier to treat.
- Indications for urgent treatment (treatment should be delayed until 5 to 6 months of age if possible) include CHF refractory to medical therapy, progressive macrocephaly, developmental delay, the development of hydrocephalus or calcification, and the development of neurologic symptoms.
- The venous drainage of the malformation and normal brain is the most important factor influencing the clinical presentation and long-term prognosis.
- In terms of treatment, heart failure requires medical treatment. Transarterial embolization is the first choice. Transvenous embolization is indicated in limited cases. Surgery is not indicated as a primary treatment. Radiosurgery is sometimes indicated for older children with a small residual.
- The hydrocephalus associated with VGAM is usually nonobstructive. Shunt surgery should be avoided if possible. Timely embolization often obviates the need for shunt surgery.
- Transarterial embolization for VGAM requires a transfemoral transarterial approach, a transumbilical artery approach for neonates, angiography at the time of treatment, a limited angiographic study (vertebral injection) for neonates, and flow-guided microcatheter embolization with NBCA (limited indication for coils).
- Transvenous embolization for VGAM requires a transfemoral transvenous or a transtorcular approach with guidewire-assisted microcatheter and coil embolization. It is usually reserved for the last stage of treatment to obtain complete obliteration.

70 Pediatric Spinal Vascular Malformations

A. Jesse Schuette, Daniel B. Case, Mark J. Dannenbaum, C. Michael Cawley, and Daniel L. Barrow

Spinal vascular malformations are a distinctly rare but important pathologic entity in the pediatric population. From low-flow lesions like cavernous malformations to larger, high-flow lesions like juvenile arteriovenous malformations, significant variability occurs that requires a neurovascular team approach to management. Although these conditions are quite rare, with some estimates of less than 1 in a million persons,¹ the morbidity associated with the disease process can be significant. Presentations in the child population are often acute and dramatic.²⁻⁴ However, with appropriate management, patients can be treated with potential cure and improvement of neurologic status.

The first description of spinal vascular malformations was made by Virchow in 1865.⁵ At that time, they were felt to be neoplasms of the spine. The first surgery for a spinal vascular malformation, in a 13-year-old boy, was reported in 1912 by Charles Elsberg.⁶ The patient's condition did not improve after surgery. Later attempts concentrated on dural arteriovenous fistulas with venous stripping, but successes were relatively few. A spinal vascular malformation was first imaged in 1927 by Perthes, who used Pantopaque myelography.^{5,6} A true understanding of this class of disorders and their anatomy began with the use of spinal angiography in the 1960s.

In this chapter, we discuss the different anatomical types of spinal vascular malformations, highlighting their diagnosis and treatment. We also address syndromes that can be associated with these malformations. It should be noted that numerous classification systems have been used for spinal vascular malformations, mostly based on anatomical considerations. The most frequently used systems divide vascular malformations with shunting into four types: type I, spinal dural arteriovenous fistula (AVF); type II, intramedullary arteriovenous malformation (AVM); type III, juvenile diffuse AVM, or Cobb syndrome; and type IV, perimedullary AVF (► Fig. 70.1). Spetzler et al have recently added the conus AVM as a separate entity.⁷ Type I spinal dural AVF, although the most common type in adults, is an acquired lesion and is not found in children with any frequency.³ Cavernous malformations (CMs) are discussed in detail separately.

70.1 Spinal Intramedullary Arteriovenous Malformations

Intramedullary AVMs (type II) are true intramedullary malformations with a nidus interposed between multiple feeding arteries and draining veins that involve the substance of the spinal cord.⁶ Often referred to as glomus AVMs, these lesions are high-flow and high-pressure systems with an arterial supply derived from the anterior and/or posterior spinal arteries (► Fig. 70.2).

Uncommon in the general population, spinal AVMs in children account for a small percentage of the cases of this rare disease.^{3,8} The morphology of the malformations does not differ from that of the adult lesions per se, but the presentation and morbidity can differ. These are important clinical entities

because they produce considerable morbidity and may even be fatal if left untreated.

Treatment strategies are unique because pediatric diseases carry a complex set of variables that must be incorporated into treatment planning. In the later pediatric presentation, the disease features tend to more closely resemble those of the adult disease process, so it is postulated that the early pediatric presentation may be a severe form of the adult disease process.²

Like perimedullary fistulas, juvenile-type AVMs in the pediatric population are seen more often in boys than in girls.^{2,3} Pediatric intramedullary AVMs more often present with a history of progressive and fluctuating myelopathy and with episodes of acute neurologic deterioration secondary to hematomyelia.^{2,3} The lesions often involve the dorsal thoracic spine or conus medullaris.⁸ Some authors advocate placing conus medullaris AVMs in a distinct category.⁹

Unlike type III AVMs (spinal arteriovenous metameric syndrome [SAMS], or Cobb syndrome), which are extensive congenital vascular malformations, and type IV AVMs (perimedullary AVFs), which can be associated with syndromes like hereditary hemorrhagic telangiectasia (HHT), type II spinal AVMs are usually spontaneous.¹⁰

70.1.1 Incidence and Prevalence

Spinal AVMs are underdiagnosed in the general population because of their variable and complex presentation, resulting in an estimation of the incidence of the disease rather than the true incidence. Estimations of 3.3 to 11% of all spinal cord lesions and 10% of all central nervous system (CNS) AVMs are reported in the current literature on the subject.^{11,12} These estimations are based on single-institution experiences with relatively small sample sizes, in large part as a consequence of the rarity of the disease.

Disease incidence is less frequent in the pediatric population. Berand in 1972 retrospectively reviewed 304 cases of AVMs of the spinal cord and found that 1.9% of patients were younger than 10 years and that 13% were younger than 20 years.¹³ Rodesch et al¹⁴ reviewed 155 patients with CNS arteriovenous shunts between the years of 1981 and 1999 (single institution) and found pediatric spinal AVMs to account for 5% of all CNS AVMs and for 20% of AVMs of the spine. Of the four types, types II and III are more commonly diagnosed in children and young adults.

70.1.2 Natural History and Presentation

Given the rarity of this disease, it is not commonly considered in the differential diagnosis, especially because of the lack of specific presenting clinical symptoms. Symptoms reported in the literature include neck, chest, and back pain; sensory and motor deficits; bowel and bladder dysfunction; headache; altered mental status; meningeal symptoms; and spinal bruit.^{3,15–18} Children more commonly present with an acute onset of symptoms than do adults.^{3,10} A review of 72 cases of pediatric spinal vascular malformation found a 52.8% incidence of acute presentation versus a 30.6% incidence of chronic, progressive symptom presentation for intramedullary spinal cord AVMs.³ An acute presentation often is a result of hemorrhage, either hematomyelia or subarachnoid hemorrhage.^{3,8}

The presenting symptoms can differ between extremely young children (younger than 2 years) and children younger than 15 years. Case studies of children younger than 2 years showed that they presented with a significantly lower incidence of hemorrhage, either hematomyelia or subarachnoid hemorrhage, than did children younger than 15 years.¹⁹ Cullen et al reported an incidence of hemorrhage of 23% in patients younger than 2 years with spinal AVMs versus an incidence of up to 67% in pediatric patients younger than 15 years.²

Initial estimates of disease progression and a poor prognosis for children with these lesions were likely influenced by the dural AVF literature.^{2,6} Unlike those who present with spinal cord AVFs, patients who present with hemorrhagic intramedullary AVMs usually improve without treatment. Cullen et al showed that 72% of pediatric patients improved, with only 20% showing worsening symptoms.² Interestingly, recurrent hemorrhage was seen in only 9% of patients.² These data support the concept that observation may be a reasonable option for patients in whom surgery is associated with unacceptable risk.

70.1.3 Treatment

The gold standard for the treatment of intramedullary AVMs remains microsurgical resection.^{6,8} Surgery can usually be approached with a posterior laminectomy or posterolaterally with a transpedicular exposure. General surgical outcomes for pediatric patients are better than those for their adult counterparts. A review by Kalani et al in 2012 reported the results of treatment of spinal AVMs at a high-volume center.⁸ Three of the patients were treated with surgery alone with good results.

Endovascular treatment provides an adjunct and, in some rare cases, an alternative to surgery for intramedullary and conus medullaris AVMs. If embolization is planned, some authors advocate spinal provocative testing to aid superselective angiography.^{8,20,21} In these cases, amobarbital (Amytal; Marathon Pharmaceuticals, Deerfield, IL) and lidocaine can be injected to test for clinical or neuromonitoring changes. If the test is negative, embolization can be completed with *N*-butyl-cyanoacrylate (NBCA) or Onyx (Micro Therapeutics [Covidien], Mansfield, MA). No clinical studies have compared the efficacy of embolization versus that of open microsurgical treatment.

At this time, the treatment for this complex lesion should begin with a high-quality spinal angiogram to assess its angioarchitecture.^{8,22} If there are pedicles to the AVM that can be traversed safely with a microcatheter without endangering the anterior or

posterior spinal arteries, an embolization can be attempted.²¹ Complete cures by embolization have been reported, although they are in the minority.^{8,22} After embolization, the majority of patients require surgical resection. The recommendation for resection should be made on individualized case-by-case basis. Although complete resection is the goal, the surgeon must recognize the limits of the resection and identify vessel loops that may leave a permanent deficit if chased into the spinal cord parenchyma. Velat et al described the resection of these lesions with a subtotal pial resection method, which devascularizes the AVM without violating the spinal cord parenchyma.²³ All patients should undergo postoperative angiography and, if possible, intraoperative angiography to document the extent of the resection.

Stereotactic radiosurgery currently does not have a treatment role in this patient population, considering the small size of the cord and the anticipated long life expectancy of the patients.¹⁰

70.2 Spinal Arteriovenous Metameric Syndrome/Cobb Syndrome

Spinal arteriovenous metameric syndrome (SAMS) is an extremely rare disorder that is nonheritable. It is characterized by a vascular malformation that extends beyond the spinal cord and involves the bones, paraspinal, skin, and soft tissues that arose from the same metamere^{24,25} (► Fig. 70.3). Cobb syndrome represents involvement of the entire metamere. The syndrome has previously been classified as a type III or juvenile AVM and is often referred to as an intradural–extradural AVM. Rodesch et al postulated that other genetic nonheritable syndromes, such as Klippel-Trénaunay syndrome and Parkes Weber syndrome, represent a lesser spectrum of these metameric disorders with multiple AV shunts.¹⁴

70.2.1 Incidence and Prevalence

The actual incidence of Cobb syndrome is difficult to estimate. The first report of the syndrome was in 1890.²⁵ It was not truly recognized until 1915, when Cushing deduced that Cobb had had a patient with an underlying spinal AVM in addition to the cutaneous findings. Overall, the complete metameric syndrome has been reported in fewer than 50 patients in the literature.²⁴ Like other pediatric spinal malformations, it shows a male predilection.³

70.2.2 Natural History and Presentation

Cobb syndrome presents equally with acute and chronic symptoms.^{4,24,26} Classically, acute presentations have a rapid monoparesis or paraparesis with loss of bladder or bowel function.^{25,26} Chronic symptoms include progressive back or radicular pain, progressive weakness and numbness, and bladder and bowel involvement. The natural history of Cobb syndrome remains unpredictable, with disease rapidly progressing in some patients and stabilizing in others.¹⁰ There are currently insufficient data to identify the prognosis accurately, although of the 5 identified patients treated conservatively, 2 worsened, 2 improved, and 1 stabilized.²⁴ In fact, Malis reported that “their rarity is perhaps the only favorable aspect of these lesions.”²⁷

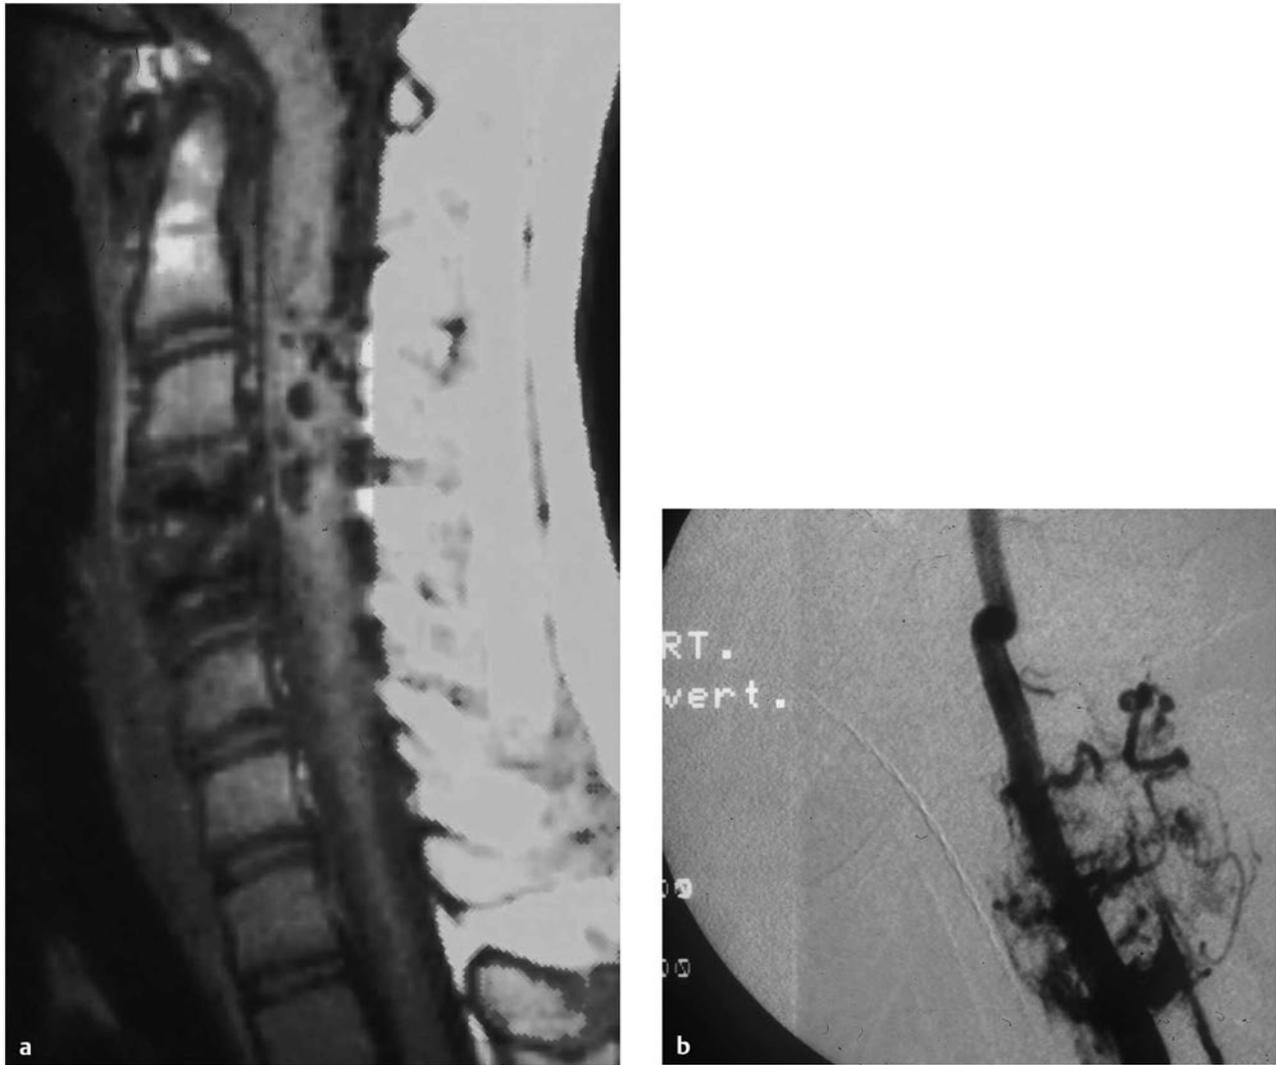

Fig. 70.3 (a) Magnetic resonance image and (b) angiogram showing a metamerically spinal arteriovenous malformation.

70.2.3 Treatment

The treatment of Cobb syndrome rarely results in complete resection of the AVM.^{8,24} Reports in the literature have described combined embolization and surgical resection resulting in complete cure, although they are rare.^{28,29} The goal for the treating physician should be to disconnect large feeding vessels with embolization and to combine this embolization with surgery to decompress the nerve roots and spinal cord, if possible.⁸ Often, embolization alone can reduce symptoms by decreasing venous hypertension and vascular steal. Additionally, some authors add corticosteroid administration and radiation treatment to surgery or embolization.³⁰ Clark et al published a review of patients with Cobb syndrome.²⁴ Seventeen patients underwent surgery alone, with seven reported improvements. Six underwent combined embolization and surgery, with five showing improvement. Overall, each case should be approached individually to assess what is best for the pediatric patient. Often, surgical resection should be avoided in a very young patient because of the potential for excessive blood loss.

70.3 Perimedullary Arteriovenous Fistula

Type IV AVMs are intradural, perimedullary, direct AVFs on the (usually ventral) pial surface of the cord between the anterior and/or posterior spinal arteries and the medullary veins (► Fig. 70.4). These fistulas were first described by Djindjian et al.³¹ Anson and Spetzler further subclassified them as types IV-A, IV-B, and IV-C based on their size and flow characteristics.⁷ Type A is a small fistula with minimal shunting and minimal venous hypertension, type C is a large fistula with high flow and significant venous ectasia, and type B is intermediate between type A and type C. Other authors have divided perimedullary fistulas into microfistulas (IV-A) and macrofistulas (IV-B and IV-C). A macrofistula in a pediatric patient is often correlated with HHT and may be the presenting manifestation of the disease.

70.3.1 Incidence and Prevalence

The incidence of perimedullary fistulas in the pediatric population is difficult to assess. Cullen et al estimated the total incidence of spinal arteriovenous shunts to be 1 in 1 million patients of all ages, with 20% of these patients in the pediatric age group.¹⁰ Du et al reported that 1.4% of all spinal vascular malformations are pediatric perimedullary AVFs.³

70.3.2 Natural History and Presentation

A review of 72 cases of pediatric spinal vascular malformation found the incidence rates of acute and chronic presentations to be equal in patients with perimedullary AVF.³ In most patients presenting with this type of spinal shunt, the manifestation of the fistula is related to venous hypertension and/or mass effect on the spinal cord.⁶ Although less often the case, subarachnoid hemorrhage may also occur. Perimedullary fistulas most commonly develop in the thoracolumbar region at the conus medullaris of the spinal cord.^{3,6,32}

The natural history of perimedullary AVFs is generally believed to be poor, even though there are no long natural history studies in pediatric patients. Most authors agree that the clinical course is one of progressive deterioration and recommend treatment. Additionally, any child presenting with a perimedullary AVF should be screened for HHT before treatment.^{3,8}

70.3.3 Treatment

The treatment of perimedullary AVFs must concentrate on disconnection of the point of arteriovenous shunting. Currently, most authors recommend endovascular embolization of the AVF initially with or without surgical resection.^{6,8} Embolization should concentrate on passing the catheter as close to the fistulous point as possible and injecting NBCA or Onyx through the fistula to the proximal venous drainage.^{8,32} In some cases, surgery may be required because of anatomical limitations or to remove mass effect from engorged venous structures.

Outcomes of the treatment of perimedullary fistulas are good to excellent in reported series, with improvement or stabilization noted in most patients. Rodesch et al in 2003 published their results on the embolization of spinal cord shunts.³³ Of the 69 patients, 20 were children, and 80% of the children showed clinical improvement. Cullen et al reported on 8 patients with fistulas who received endovascular treatment. Of the 8, 6 had 100% reduction of the fistula and the remaining 2 had 90% reduction.² Improvement of symptoms was noted in 6 of the 8, and the remaining 2 had stabilization of disease. Additionally, there have been numerous case reports of pediatric perimedullary fistulas treated with embolization or a combination of embolization and surgery that demonstrated improvement after treatment.^{32,34}

70.4 Cavernous Malformations

A CM is a thin-walled sinusoidal cavity with very slow to stagnant blood flow.^{35,36} These lesions were initially found only when they hemorrhaged into neural tissue. With the advent of magnetic resonance (MR) imaging, they are now often discovered incidentally. The MR imaging appearance of a CM is that of

a heterogeneous, reticulated, “popcorn-like” mass of mixed signal intensities that correspond to intralesional hemorrhage at various stages of evolution with a hypointense rim of surrounding hemosiderin-laden parenchyma (► Fig. 70.5). These lesions were initially referred to as angiographically occult vascular malformations because of the relative difficulty of visualizing them on a diagnostic angiogram.

The location of a CM may be intramedullary, extramedullary–intradural, epidural, or vertebral. We concentrate primarily on intramedullary CMs.³

70.4.1 Incidence and Prevalence

CMs have been reported in the literature since the late 1800s but were originally believed to be a rare lesion. With the advent of MR imaging, a more accurate incidence has been realized. Currently, CMs are thought to be present in 0.4 to 0.8% of the population.³⁷ Of this number, approximately 25% are in the pediatric patient group.³⁸ CMs are the most common CNS vascular malformation in the pediatric age group.^{3,38,39}

As in adult patients, the vast majority of CMs present in the supra- or infratentorial regions of the brain. Only 5% of CMs present in the intramedullary compartment, and, of that number, 10% occur in the pediatric setting.³⁹ In a review from 2001, roughly 12 pediatric CMs had been reported in the literature, with only small case series and reports published since that time.³⁹ Interestingly, a male preponderance of spinal CMs, at almost 2:1, is observed, although the number of cases is small. Some case series report more cervical lesions, whereas others suggest a thoracic majority.^{38–40} Spinal CMs have also been reported in the literature after spinal radiation.^{41,42}

70.4.2 Presentation

In 50 to 75% of cases, children present with an acute neurologic decline due to hemorrhage of the CM.^{38,40} In these cases, the patient will show acute myelopathy, with paraparesis or paraplegia and pain in the region. This is in contrast to adult patients, who often present with slowly progressive myelopathy.⁶ Children may have a slower, more chronic presentation, with progressive numbness, ataxia, hemiparesis, and ultimately pain. The typical time from symptom onset to diagnosis in children is 1 to 12 weeks.^{38,39}

70.4.3 Natural History and Treatment

The natural history of intramedullary pediatric CMs is not clearly understood, although estimates of the hemorrhage rate range from 1.4 to 1.7% per lesion per year.⁴³ In the adult literature, small numbers of patients followed conservatively with stabilization of symptoms have been reported.^{44,45} There are insufficient data in the pediatric population. The current recommendations are that treatment should be offered to any patient with neurologic decline or progressive myelopathy.

Currently, the only proven treatment for pediatric spinal CMs is complete and total microsurgical removal.^{6,45} Partial resection of a CM provides no benefit to the natural history of the lesion, with multiple repeated hemorrhages reported in the pediatric literature. Many authors recommend the use of intraoperative monitoring, although this has not been shown to improve outcomes.⁴⁶

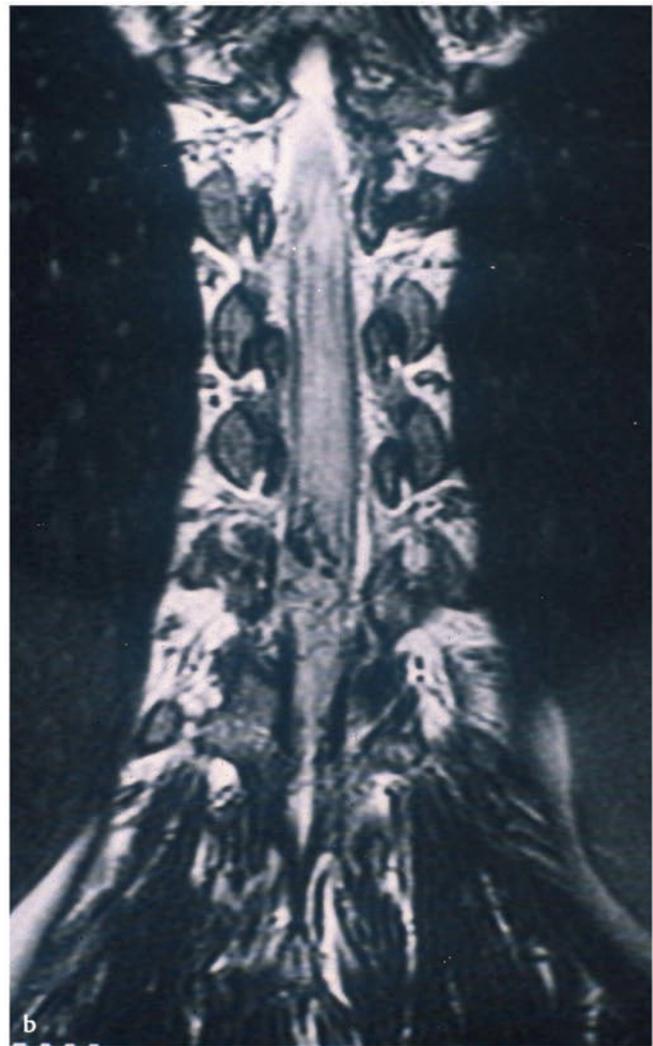

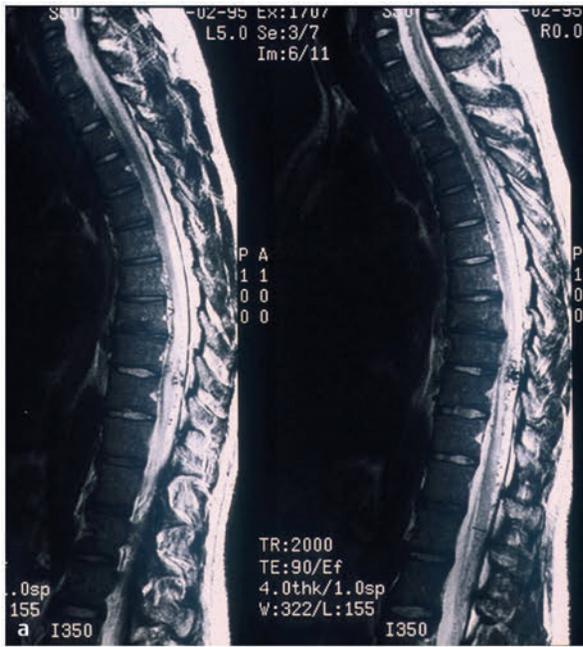

Fig. 70.4 (a,b) Magnetic resonance images showing a perimedullary fistula in a pediatric patient. (c) Angiogram confirming the diagnosis of perimedullary arteriovenous fistula.

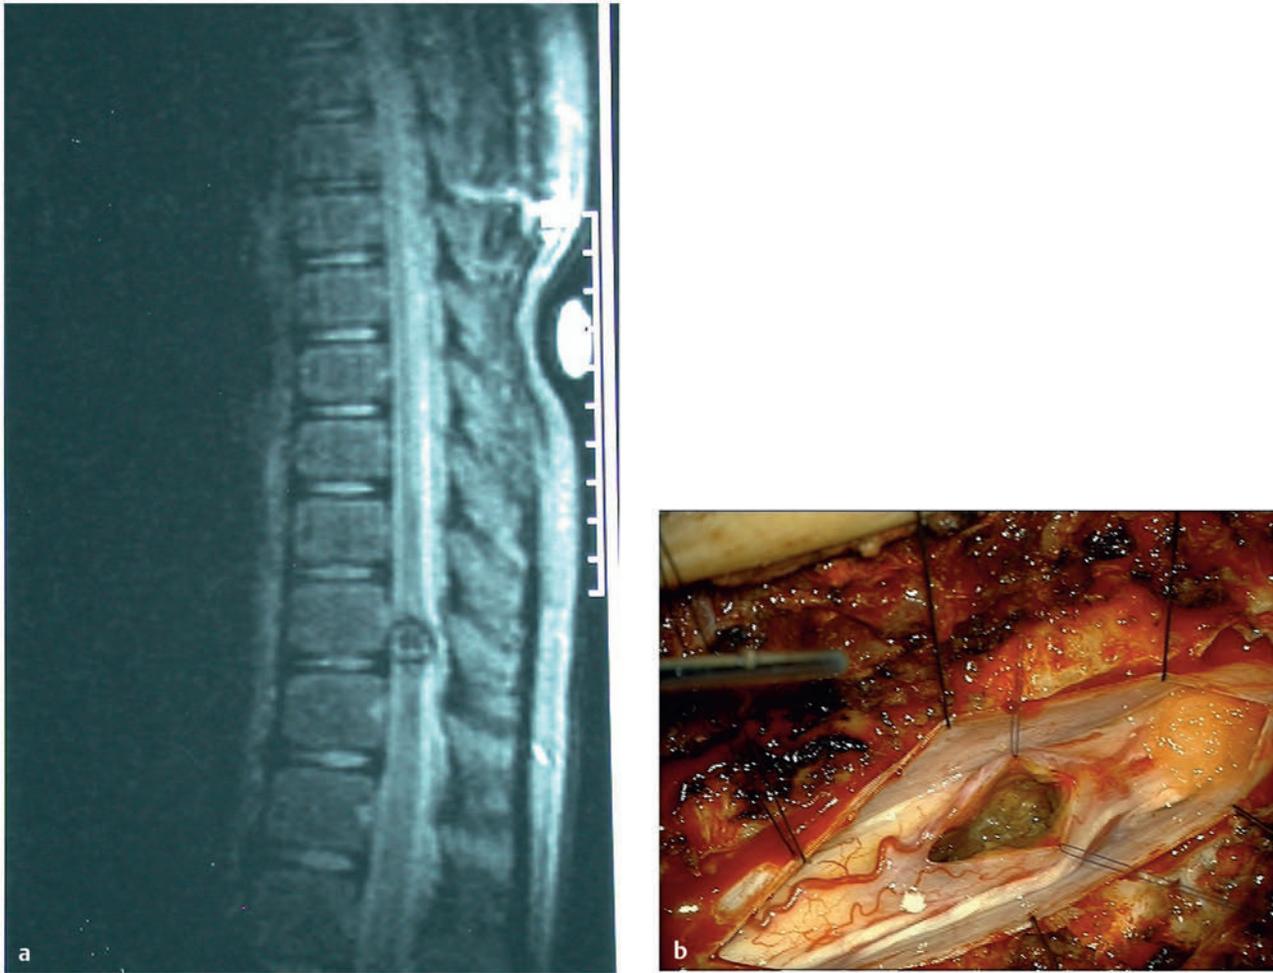

Fig. 70.5 (a) Magnetic resonance image of an intramedullary cavernous malformation (CM) in a young teenager. (b) Intraoperative image showing an intramedullary CM during resection.

Surgery proceeds similarly to adult cases. Most CMs can be reached by a standard laminectomy or laminotomy.⁴⁶ In some cases of more ventrally located lesions, a transpedicular approach with release of the dentate ligament can be utilized. In this age group, most surgeons avoid spinal fusion if possible.

The resection of a CM should take place at the point where it abuts the pial plane. If the CM is deep and midline, a midline myelotomy can be used.^{46,47} Entry into the dorsal root entry zone can be used in laterally oriented lesions. As in all spinal cord surgeries, entering the cord ventrally should be avoided if at all possible. Surgical results in the pediatric population are generally good, with one study reporting 83% of patients with symptom stability or improvement.³⁹ The degree of improvement is related to the patient's preoperative status, with early surgery before the development of severe deficits resulting in the best outcomes.

Stereotactic radiosurgery has not been established as an effective treatment for pediatric CMs.^{38,39} Additionally, the risks of radiation treatment to children far outweigh any theoretical benefit of the treatment.

70.5 Syndromic Associations

Several syndromes due to genetic mutations are associated with spinal vascular malformations. It is important to be familiar with these syndromes in the pediatric population because these patients typically present at an early age, some before 2 years of age.

The most common syndrome associated with spinal arteriovenous shunts is HHT.^{10,48} HHT is an autosomal-dominant angiodyplasia with variable expression and high penetrance.⁴⁸ The classic definition of the disorder includes the triad of epistaxis, telangiectasias of the lips and fingertips, and a family history. These patients have arteriovenous shunts in pulmonary, hepatic, and CNS circulations. The most common neurologic complications are often embolic as a result of pulmonary shunting, not primary CNS shunts. The incidence of the disorder is 1 in 5,000, although this may be an underestimation.¹⁰

An estimated 10 to 20% of patients with HHT have intracranial or intraspinal shunts.⁴⁹ Most authors recommend screening for intracranial vascular lesions within 6 months of the

diagnosis, although spinal screening is not routinely performed. In a review of 50 consecutive patients with HHT in France, 7 patients were found to have spinal arteriovenous shunts, all perimedullary macrofistulas.⁴⁹ Also, an analysis of 13 cases of spinal arteriovenous shunt in patients younger than 2 years showed 6 patients who had HHT, with 5 perimedullary fistulas and 1 spinal intramedullary AVM.² Patients who carry the diagnosis of HHT and present with spinal AVMs should be screened with MR imaging of the neuraxis to assess for other malformations.

Nonheritable syndromes are also associated with spinal arteriovenous shunts. Type III spinal malformation, or Cobb syndrome, is also termed spinal arteriovenous metamerism syndrome (SAMS).¹⁰ In a review of 13 spinal vascular malformations in patients younger than 2 years, 15% of patients had SAMS.² This disorder is described above.

Several additional syndromes are associated with arteriovenous shunts, namely Klippel-Trénaunay syndrome and Parkes Weber syndrome.¹⁰ Both syndromes are extremely rare and are due to a somatic mutation. Patients with Klippel-Trénaunay syndrome generally present with port-wine stains, varicose veins, and hypertrophy of bone and soft tissue. Parkes Weber syndrome results from a mutation in the *RASA1* gene and is characterized by multiple arteriovenous fistulas along with port-wine stains and overgrowth of a limb.⁵⁰ Some sources combine the two disorders. These patients often present with multifocal AVFs.

Since 1988, when Rigamonti et al found that 54% of CMs have a strong pattern of familial inheritance, it has been well known that familial CMs are not rare.⁵¹ They appear more often in Hispanic families, inheritance is autosomal-dominant, and affected persons present with multiple cerebral CMs.^{51,52} Three genes have been identified that are associated with familial CMs: *CCM1*, *CCM2*, and *CCM3*.^{52–55} Although the incidence of spinal CMs in cases of familial inheritance is unknown, studies have indicated that between 42 and 47% of patients may have coexisting intracranial and spinal CMs.⁵⁶ Some authors recommend adding spinal MR imaging to the work-up at initial presentation.

Pearls

- Although rare in the pediatric population, spinal vascular malformations pose a significant risk to patients who harbor the disease.
- Type I spinal dural AVFs, the most common type in adults, are not found with any frequency in children.
- Glomus AVMs present most commonly with hemorrhage and are treated with surgery with or without preoperative embolization.
- Type III juvenile spinal AVMs are extremely rare and generally not resectable with surgery.
- Type IV perimedullary fistulas present with chronic symptoms of venous hypertension and are amenable to endovascular treatment with or without surgical resection.
- Spinal CMs require surgical excision. Treatment is offered to any patient with neurologic decline or progressive myelopathy.

71 Evaluation of Intractable Epilepsy in Children

M. Scott Perry and Michael Duchowny

Epilepsy is the tendency to have more than one unprovoked seizure. The incidence of epilepsy is highest in the first years of life, and the majority of cases of childhood-onset epilepsy ultimately remit. Antiepileptic drugs (AEDs) remain the first line of treatment, with approximately 50% of patients achieving seizure freedom with their first medication trial and another 15% becoming seizure-free with a second medication.¹ Unfortunately, in 15 to 30% of patients, epilepsy remains medically intractable, defined as a failure of adequate trials of two tolerated and appropriately chosen AEDs to achieve seizure freedom.² Failure of therapy relies on the perception of the patient, parents, and physician that the medical treatment is not achieving an acceptable outcome. Infrequent seizures or a short duration of epilepsy does not exclude epilepsy from being intractable because both may still contribute to a significant medical risk. Even yearly seizures can exclude a patient from driving and adversely impact quality of life. Likewise, some patients present with frequent, disabling seizures for which intractability is rapidly determined, and surgical therapy may provide improvement in development. For those patients in whom intractable epilepsy develops, the evaluation can be extensive and is often carried out in specialized epilepsy centers well versed in the unique characteristics of pediatric epilepsy. The treatment strategies for such patients are complex and commonly include epilepsy surgery, neuromodulation, dietary therapy, and additional trials of medications used alone or in combination to achieve cure or palliation of symptoms.

71.1 Patient Selection

71.1.1 Pseudo-intractability

The process of labeling a child's epilepsy as intractable may seem straightforward based on the operational definition of failure of two prior AED trials; however, one must first determine that the AEDs used were appropriate for the type of epilepsy. For example, the idiopathic generalized epilepsies typically respond very favorably to adequate treatment, and most treatment failures result from an inaccurate diagnosis of the epilepsy type or a poor choice of medication.³ Persistent uncontrolled seizures in a patient with juvenile myoclonic epilepsy who is on carbamazepine monotherapy should not be unexpected because this drug may worsen clinical seizures. Likewise, it is important to carefully delineate whether medication failure is secondary to adverse effects or whether failure has occurred after maximum dosing titrations, because tolerability of the treatment is a prerequisite for efficacy. In rare circumstances, the sedative effects of an AED can lower the seizure threshold and paradoxically increase seizure frequency. In a recent review of patients with pseudo-intractable epilepsy who ultimately became seizure-free following medication changes, therapeutic errors (i.e., inadequate dosing of medications) were implicated as the cause of intractability in 48% of cases, followed by inaccurate

diagnosis of the seizure or syndromic type (47%) and medication noncompliance (14%).⁴

Equally important to ensuring that the treatments used were appropriately chosen and administered is demonstrating that the events being treated are epileptic in origin. Numerous behaviors incorrectly characterized as seizures can be encountered in children (see box "Childhood Disorders That May Mimic Epilepsy (p.932)"), and timely evaluation with video electroencephalography (EEG) can eliminate the need for an extensive evaluation of presumed intractable epilepsy.

Childhood Disorders That May Mimic Epilepsy

- Behavioral disorders
 - Staring spells, inattention
 - Psychogenic nonepileptic seizures
 - Breath-holding spells
 - Self-stimulatory behaviors
- Movement disorders
 - Focal dystonias
 - Nonepileptic myoclonus
 - Motor tics or stereotypies
- Cardiogenic disorders
 - Vasovagal syncope
 - Arrhythmia (long QTc syndrome)
- Other
 - Cataplexy

71.1.2 Assessment of Surgical Candidacy

Multiple historical features suggest a low likelihood of seizure remission. Most are recognizable early in the course of treatment, and the threshold for referring these children for further evaluation should be low (see box "Historical Features That Predict Evolution to Intractable Epilepsy (p.933)"). Childhood-onset epilepsy differs significantly from adult-onset cases, and several etiologies and syndromes are unique to the pediatric population (► Table 71.1). In many cases, the etiology may become clear only as the epilepsy evolves; thus, the history obtained by the clinician must include a detailed description of the seizures from the outset, such that idiopathic epilepsies of childhood, which ultimately remit, and those of symptomatic genetic origin (i.e., *SCN1A* mutations), which are unlikely to benefit from surgical therapy, are considered in the correct context. At the same time, there are several pediatric epilepsy syndromes and etiologies for which surgical therapy is especially efficacious and should be considered early in the course of treatment. Lastly, infants and young children differ in that catastrophic presentations of epilepsy may require more urgent surgical evaluation to prevent epileptic encephalopathy and loss of neurodevelopmental status.

Table 71.1 Intractable epilepsy syndromes that may not benefit from surgical therapy and etiologies that respond favorably to surgery

Syndrome	Clinical findings	Recommended testing
Dravet syndrome (severe myoclonic epilepsy of infancy)	Frequent or prolonged febrile seizures in infancy Myoclonic and hemiclonic seizures after the age of 1 year Developmental regression after onset	<i>SCN1A</i> gene testing
Epilepsy and mental retardation limited to females	Frequent febrile seizures in infancy Frequent seizure clusters with tonic or generalized tonic-clonic seizures Myoclonic seizures less often than in Dravet syndrome Variable developmental delay	<i>PCDH19</i> gene testing
CDKL5 syndrome	Early onset of infantile spasms Evolution to multiple seizure types Encephalopathy	<i>CDKL5</i> gene testing
Autosomal-dominant nocturnal frontal lobe epilepsy	Early childhood focal seizures in non-rapid eye movement (REM) sleep Lifelong seizures with spontaneous remissions and relapses	<i>CHRNA4</i> , <i>CHRN2</i> , <i>CHRNA2</i> gene testing
Etiologies of intractable epilepsy for which surgical therapy may be considered a treatment of choice ⁵⁴		
<ul style="list-style-type: none"> • Sturge-Weber syndrome • Hemimegalencephaly • Rasmussen encephalitis 	Low-grade cortical tumors Hippocampal sclerosis Focal cortical dysplasia	

Historical Features That Predict Evolution to Intractable Epilepsy

- History of multiple seizure types^{49,50}
- History of infantile spasms^{50,51}
- Onset of seizures in infancy^{52,53}
- Remote symptomatic etiology^{51,52}
- Abnormal neurologic examination^{50,53}
- Frequent seizures (daily or weekly) before treatment^{50,52}
- Early recurrence of seizures (within 6 to 12 months of treatment)⁵⁰
- History of status epilepticus before diagnosis^{49–51}
- History of neonatal seizures^{49,51}
- Mental retardation⁴⁹
- Seizure clustering⁵³

71.2 Components of a Surgical Evaluation

Once intractable epilepsy has been diagnosed, the focus turns to determining an etiology, locating the source of the seizures, and evaluating the treatment options. A surgical evaluation is frequently undertaken, especially in patients with focal-onset seizures of symptomatic or cryptogenic etiology, for whom an excisional procedure may provide a cure. Even for patients unlikely to be cured, such as those with multifocal epilepsy, symptomatic or cryptogenic generalized epilepsy, or mixed seizure

disorders, surgery may provide palliation, with efficacy equal or superior to that of alternative therapies.

The presurgical assessment should take place in a pediatric epilepsy center specializing in the evaluation of intractable epilepsy because the process is complex, and a team approach is required to develop successful treatment strategies. Every surgical evaluation must begin with a detailed description of each seizure type the patient has experienced because ictal semiology typically provides important localizing information (► Table 71.2). The ictal semiologies encountered in children are unique in that features may evolve throughout early childhood as the brain develops. In infancy, complex behavioral changes and stereotyped motor manifestations are less frequently encountered, likely because of immature neuronal networks.⁵ Typical lateralizing features of adult epilepsy (i.e., head version) are of less value in infants; the automatisms of infants are more often characterized by chewing or sucking, unlike the more stereotyped behavioral manifestations observed in older children and adults.^{6–8}

Intrinsic cerebral networks that inhibit seizure propagation develop over the first decade of life, at which time the typical lateralizing patterns of adult epilepsy begin to emerge. When patients are being evaluated for palliative surgical procedures, it is important to understand the frequency for each seizure type and the impact of the seizure type on quality of life. For example, while atypical absence seizures may be the most frequent seizure type in patients with Lennox-Gastaut syndrome, it is atonic seizures that lead to significant craniofacial injury and for which surgical treatment is often efficacious.

Table 71.2 Lateralizing and localizing seizure semiologies

Semiologic pattern	Commonly associated lateralization/localization
Auras	
Psychic (emotion, déjà vu)	Temporal lobe, limbic system
Nausea	Insular cortex, frontal operculum, mesial temporal lobe
Olfactory, gustatory sensations	Limbic system, olfactory bulb, insular cortex
Ictal features	
Head version	Contralateral hemisphere, motor area anterior to precentral gyrus
Eye version	Contralateral hemisphere, frontal eye field
Unilateral clonus	Contralateral hemisphere, primary motor cortex
Homonymous positive visual phenomena	Contralateral primary visual cortex
Asymmetric tonic posturing (flexion of one upper extremity, extension of the other)	Supplementary motor cortex contralateral to extended upper extremity
Unilateral eye blinking	Ipsilateral hemisphere
Unilateral automatism	Ipsilateral mesial temporal lobe or contralateral temporal neocortex
Unilateral somatosensory paresthesias	Contralateral somatosensory cortex or supplementary sensory motor area
Postictal features	
Receptive aphasia/dysphasia	Temporal lobe, dominant hemisphere (Wernicke area)
Expressive aphasia/dysphasia	Inferior frontal gyrus, dominant hemisphere (Broca area)
Hemiparesis/hemiplegia	Contralateral hemisphere, motor cortex

Table 71.3 Characteristics and purpose of components used in the surgical evaluation of childhood-onset epilepsy

Modality	Spatial resolution	Temporal resolution	Contribution
Scalp electroencephalography (EEG)	Poor	Very good	Localization of seizure onset and interictal regions of irritability/dysfunction
Magnetic resonance (MR) imaging	Very good	Poor	Anatomical definition of epileptogenic lesions
Positron emission tomography (PET)	Good	Good	Localization of focal regions of hypometabolism corresponding to epileptogenic cortex
Single photon emission computed tomography (SPECT)	Good	Good	Localization of focal hyperperfusion corresponding to ictal onset
Magnetoencephalography (MEG)	Good	Very good	Localization of spike clusters with dipole maps, mapping of eloquent cortex
Functional magnetic resonance imaging (fMRI)	Good	Good	Mapping of eloquent cortex
Diffusion tensor imaging (DTI)	Good	Good	Mapping of white-matter tracts

A detailed EEG evaluation, preferably with video, provides the foundation for most surgical evaluations. Children with a well-localized unilateral ictal onset more often attain seizure freedom, especially in cases with concordant interictal discharges and a recognized cerebral lesion on anatomical or functional imaging.⁹ Although patients may present with apparently generalized or multifocal EEG patterns, correlation

with detailed anatomical magnetic resonance (MR) imaging and multiple functional imaging modalities may reveal a localized onset.¹⁰ Several anatomical and functional studies are often required in an epilepsy evaluation, each with inherent strengths and weaknesses with regard to the spatial and temporal localization of ictal onset and functional cortex (► Table 71.3).

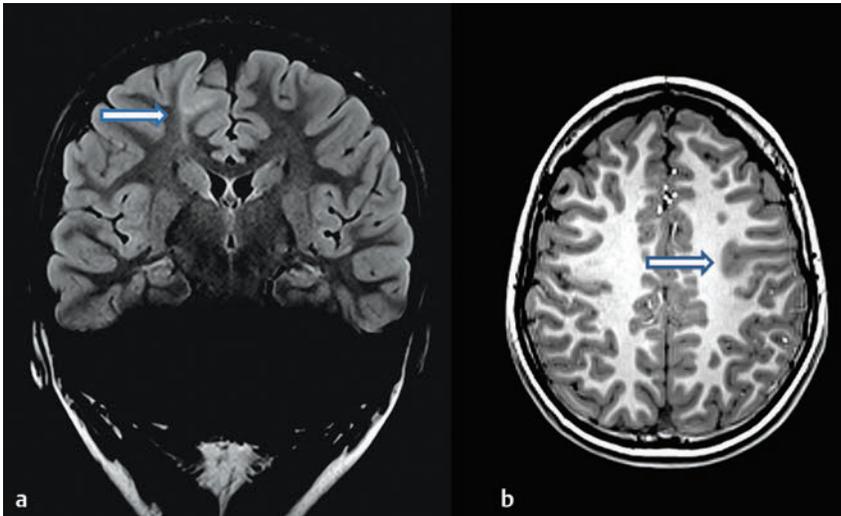

Fig. 71.1 Comparison of anatomical imaging characteristics of focal cortical dysplasia. (a) Example of transmantle sign (*arrow*) often encountered in type 2B cortical dysplasia (1.5 T [tesla], TR [repetition time] 9000, TE [echo time] 94, 3-mm slice thickness). (b) Example of cortical thickening and blurring of gray–white interface (*arrow*) seen in cortical dysplasia (3 T, TR 2100, TE 2.93, 1-mm slice thickness).

Anatomical high-resolution MR imaging with thin-slice volumetric T1-weighted gradient-recalled echo, in addition to axial and coronal T2, fluid-attenuated inversion recovery (FLAIR), and high-resolution T2 coronal imaging of the hippocampus provides excellent spatial localization of epileptogenic cortex and a basis for co-registering other imaging modalities. The most commonly encountered etiology of intractable focal epilepsy in children is focal cortical dysplasia, reported in more than 50% of cases in pediatric surgical series.^{11,12} Features of focal cortical dysplasia on MR imaging include focal cortical thickening, blurring of the gray–white junction, and increased gray matter signal on T2 or FLAIR imaging. The transmantle sign, characterized by a hyperintense white matter streak extending radially from the cortex to the lateral ventricle, may be encountered in higher-grade focal cortical dysplasia^{13–15} (► Fig. 71.1). Some of these features are more clearly delineated with post-processing techniques, such as voxel-based morphometry. The addition of 3-tesla MR imaging improves anatomical definition and will identify lesions in 65% of patients with previously reported negative findings on MR imaging.¹⁶ Difficulties may arise, however, when the substrate for epileptogenesis has a very subtle or no abnormality on MR imaging, as may occur in cryptogenic or nonlesional epilepsy. It is increasingly recognized that successful anatomical localization depends on multimodal analysis with the co-registration of other modalities, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT).¹³ Co-registration techniques may even identify epileptogenic zones beyond those identified with MR imaging, as has been demonstrated with PET and magnetoencephalography (MEG).^{17,18}

SPECT relies on cerebral blood flow, which is focally increased during a seizure and may be decreased during the interictal period. Ictal and interictal studies can be compared with direct visual analysis, although the ability of SPECT to identify the epileptogenic zone increases with postprocessing techniques, such as subtraction imaging co-registered to the MRI.¹⁹ SPECT is limited by the requirement for an early ictal radiotracer injection, but it has proved especially useful in children with a poorly defined ictal onset, multifocal cortical abnormalities on anatomical imaging, and pseudo-generalized EEG patterns.

PET is a functional imaging modality based on cortical metabolism. Focal cortical hypometabolism can identify abnormal cortex and is especially useful in patients with nonlesional extratemporal lobe epilepsy and generalized EEG patterns.²⁰ PET is performed in the interictal state, which makes it logistically easier to complete. Because the focal region of abnormality identified by PET can both underestimate and overestimate the epileptogenic zone, data should be interpreted in the context of additional studies.²¹ Postprocessing techniques, such as statistical parametric mapping, in which the patient's PET is compared with a normative PET data set to identify regions of statistically significant hypometabolism, may provide additional value.²² PET is most frequently performed with an [¹⁸F]fluorodeoxyglucose ligand, although additional ligands, such as [¹¹C]flumazenil, which binds to the γ -aminobutyric acid A receptor, and α -[¹¹C]methyl-L-tryptophan (AMT), are also used. AMT may be particularly useful when multiple potentially epileptogenic foci are present, as may occur in tuberous sclerosis.²³

MEG is increasingly being used as a diagnostic component in the evaluation of intractable epilepsy and is best regarded as complementary to EEG. Whereas EEG relies on electrical potentials, which are altered by intervening tissue such as dura, cerebrospinal fluid (CSF), and bone, to localize epileptogenic cortex, MEG relies on magnetic fields, which are unaffected. This allows a more precise localization of horizontal spike generators, with a spatial localization of 3 to 4 cm², compared with 6 to 20 cm² for EEG.^{24,25} To detect a magnetic field, the electrical current must be parallel to the skull surface; thus, MEG detects tangential dipoles well, but radial dipoles are either attenuated or invisible. MEG becomes less sensitive as the distance from the source increases, so that deep foci (i.e., mesial temporal) may not be as well localized as superficial neocortical foci.²⁶ MEG can identify interictal spikes in patients with a normal EEG and may provide important localizing information beyond that of other presurgical modalities in up to 24% of cases.^{27,28} MEG-based magnetic source imaging can also be used to map eloquent cortex with paradigms to localize sensorimotor, visual, and verbal function. MEG is currently available in only a small number of epilepsy centers in the United States, which limits its use in most presurgical evaluations. MEG requires specialized

expertise for data analysis, and as with all functional imaging modalities, the quality of the final result is largely related to the experience of the center performing the test. The utility of MEG, like that of other new technologies, will likely evolve as the standardization of data acquisition and analysis improves.

Although localization of the epileptogenic zone is of the utmost importance to the success of epilepsy surgery, it is equally important to localize the relationship of eloquent cortex to the epileptogenic zone to avoid postoperative deficits. Functional MR imaging (fMRI), commonly used to localize eloquent cortex, detects changes in regional blood flow to map function. Paradigms for mapping sensorimotor, language, and vision function can be applied successfully in children as young as 5 years of age.^{29,30} These data complement presurgical localization of the epileptogenic zone to guide subdural electrode placement. With increasing recognition of the accuracy of fMRI, the intracarotid amobarbital (Wada) procedure is rarely employed at most centers.

Additional imaging techniques, such as diffusion tensor imaging (DTI), provide important information regarding the functional connectivity of eloquent cortex, which is essential to surgical planning. The flow of water molecules along nerve fibers is restricted in the perpendicular plane (i.e., anisotropic), whereas the flow of CSF is unrestricted (i.e., isotropic). DTI uses this anisotropy to visualize white matter tracts, which can then be co-registered in multimodal analysis so that their relationship to the epileptogenic zone can be understood. DTI has anatomical accuracy comparable with that of subcortical mapping, and the presurgical appearance of DTI tracts may be useful in

predicting postsurgical deficits, with patients demonstrating displaced tracts experiencing less deficit than those in whom the tracts are included in the target lesion.³¹⁻³⁴

The individual imaging components included in a child's evaluation are dictated by the clinical circumstances of the epilepsy. For example, patients who have single well-defined cortical lesions concordant with EEG data may not require SPECT or PET but may benefit from fMRI if the lesion is in close proximity to eloquent cortex; in contrast, patients with apparently normal MR imaging findings or a poorly localized scalp EEG often benefit from PET, SPECT, or MEG to better define the region of abnormal cortex. It is generally accepted that multimodal analysis with co-registered imaging data improves localization, surgical planning (i.e., grid placement), and ultimately surgical outcome. Studies of the co-registration of MR imaging with SPECT and MR spectroscopy data demonstrate a sensitivity of 100% for focus lateralization in temporal lobe cases and particular localizing efficacy in patients with negative MR imaging results.³⁵ Similarly, PET co-registered with MR imaging may significantly improve the yield of focus localization compared with PET alone and may be especially valuable for patients with low-grade cortical dysplasia or discordant data, improving the postsurgical outcome.^{18,36,37}

To perform multimodal analysis, noninvasive presurgical imaging should be obtained in a resolution that permits three-dimensional or orthogonal representation, which in turn allows the co-registration and scaling of data. The volumetric T1 MR image most often serves as the anatomical reference image for the co-registration of all other modalities. Once imaging data

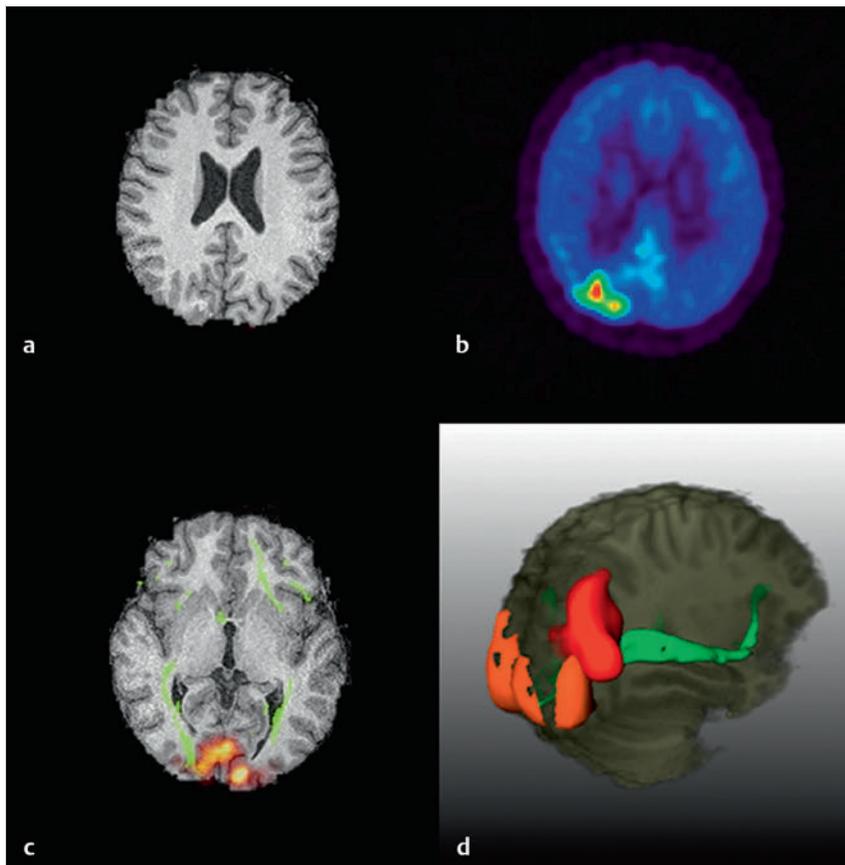

Fig. 71.2 Multimodal imaging analysis with co-registered presurgical imaging data. (a) Two-dimensional magnetic resonance (MR) imaging. (b) Positron emission tomography (PET) performed during focal status epilepticus with ictal hypermetabolism (red). (c) Functional MR imaging/diffusion tensor imaging (fMRI/DTI) with visual cortex (orange) and overlying visual tracts (green). (d) Co-registration with three-dimensional MR imaging representation and overlay of fMRI (orange), PET (red), and DTI (green).

are co-registered, a number of postprocessing techniques can be used to create overlays of each modality, providing an excellent representation of epileptogenic zone localization, grid placement, and the functional connectivity of eloquent cortex (► Fig. 71.2).

71.3 Predictors of Seizure Outcome

Once the presurgical evaluation is complete, the patient's data must be reviewed to determine candidacy for epilepsy surgery. This discussion often involves multiple medical specialists, including epileptologists, neurosurgeons, neuropsychologists, and neuroradiologists. The primary goal is to determine the likelihood that surgery will result in seizure freedom or significant seizure reduction such that the benefits of surgery outweigh the risks of the procedure. Patients referred for surgical therapy may undergo single-stage procedures for well-localized ictal onset or multiple-stage procedures in which chronic subdural or depth EEG is employed. Patients who undergo multiple-stage procedures generally have an inadequately defined epileptogenic zone or a zone of seizure onset that is in close approximation to eloquent cortex and requires more precise subdural cortical mapping.

Numerous pre-, peri-, and postoperative variables contribute to the successful outcome of epilepsy surgery, and all must be carefully considered when patients and their families are counseled regarding treatment options. Of the multiple variables that contribute to success, the most important is completeness of the epileptogenic zone resection.^{38,39} In a series of pediatric patients who had focal cortical dysplasia, 70% with complete resection remained seizure-free, versus only 22% with incomplete resection.³⁸ The definition of the epileptogenic zone continues to evolve but relies heavily on the anatomical lesion defined by MR imaging and the physiologic lesion defined by electrophysiology. Each contributes significantly, and neither alone defines the epileptogenic zone, as patients with complete resection of both the anatomic and the physiologic epileptogenic zone have a better outcome than do those with complete resection of only one of the zones.⁴⁰ In many cases, the zone of seizure onset may extend beyond the borders of the lesion evident on MR imaging; this situation is often encountered in patients with low-grade cortical dysplasias or developmental tumors bordered by dysplastic cortex. In such circumstances, complementary imaging modalities such as MEG and PET may better define the borders of the epileptogenic cortex.^{17,18}

Further definition of the physiologic epileptogenic zone relies on subdural electrophysiologic data, obtained with either intraoperative electrocorticography or prolonged extraoperative subdural encephalography. For both, accurate presurgical localization is necessary to ensure proper electrode placement. Internally, the epileptogenic zone is characterized by regions of active spiking with constant focality, focal regions of rhythmic fast activity, and associated focal attenuation of the background.^{38,39} Patients undergoing extraoperative subdural monitoring are further characterized with ictal data. Several other variables contribute to seizure-free outcome after epilepsy surgery, with many ultimately related to the completeness of resection (see box "Predictors of Seizure-Free Outcome following the Surgical Treatment of Intractable Childhood-Onset Epilepsy (p.937)").

Predictors of Seizure-Free Outcome following the Surgical Treatment of Intractable Childhood-Onset Epilepsy

- Preoperative variables
 - Older age at seizure onset⁴¹
 - Unifocal lesions on MR imaging^{40,41}
 - Psychiatric comorbidities^{57,58}
 - IQ > 70⁵⁹
- Operative variables
 - Completeness of resection^{38,39,60,61}
 - Unilobar resection^{12,40,41}
 - Temporal lobe resection^{12,41,62}
- Postoperative variables
 - Histopathology (tumor > cortical dysplasia)^{12,41}

There are some situations in which patients may be less likely to achieve seizure freedom following surgical therapy, yet they still deserve further consideration. For example, patients in whom presurgical evaluation suggests that resection of the epileptogenic zone will be incomplete, such as those with an onset zone encroaching on eloquent cortex, may still achieve seizure freedom. In a series of patients with incomplete resections, 40% achieved seizure freedom; those who had complete resection on either MR imaging or EEG were more likely to remain seizure-free than those with complete resection on neither MR imaging nor EEG.⁴⁰

Another commonly encountered circumstance is the requirement for multilobar resections, seen in 12 to 22% of pediatric series.^{41,42} Although outcome is more favorable after unilobar procedures, more than 40% of appropriately chosen patients undergoing multilobar resections remain seizure-free at 10 years postoperatively, with those undergoing extended posterior or quadrant resections faring best.⁴³ This is further discussed in Chapter 72.

For some patients, the expected surgical outcome is not seizure freedom but palliation of the most dangerous or frequent seizure type. For example, corpus callosotomy is often employed to treat atonic seizures associated with Lennox-Gastaut syndrome, which pose considerable medical risk related to fall and injury. Even in patients clearly demonstrating a multifocal ictal onset, resection of the region associated with the most debilitating seizure type can still prove beneficial.⁴⁴ For others, such as those with epileptic encephalopathies, surgical intervention may serve to prevent further cognitive decline as well as reduce seizures. Surgical therapy has been used successfully to treat Ohtahara syndrome, West syndrome, and Landau-Kleffner syndrome, achieving improvement in cognitive development in addition to seizure reduction.⁴⁵⁻⁴⁸ In all palliative cases, the goal of surgical therapy must be clearly delineated a priori in order to objectively assess the success of the procedure.

The evaluation of medically intractable childhood-onset epilepsy is a complex endeavor that requires a thorough understanding of pediatric epilepsy and the etiologies that lead to intractability. Well-performed evaluations not only localize ictal onset, but also help delineate cause, such that the recommended treatment matches the underlying etiology. Surgical therapy is an increasingly viable approach to treating intractable epilepsy,

with the spectrum of patients considered candidates steadily increasing, although surgery remains an underutilized treatment strategy. There are a number of features that predict treatment failure early on in medical therapy, and clinicians should maintain a low threshold for undertaking a more extensive evaluation as the epilepsy of these patients becomes intractable.

Pearls

- Medically intractable epilepsy is defined as the failure of two adequate trials of appropriately chosen and tolerated AEDs to achieve seizure freedom.
- Pseudo-intractability is an important concept that must be explored through careful evaluation before more extensive surgical evaluations are undertaken.
- Patients who have localization-related epilepsy with a well-defined ictal onset are excellent candidates for surgical evaluation and potential cure. However, patients with multifocal localization-related epilepsy, a symptomatic generalized epilepsy, or an ictal onset for which complete resection is not possible may still benefit from surgical therapy.
- The presurgical evaluation of intractable epilepsy requires a detailed history, neurophysiologic data, and a number of anatomical and functional imaging studies to accurately define the ictal onset zone.
- Several pre-, peri-, and postoperative variables contribute to the likelihood of seizure freedom following surgical therapy for intractable epilepsy, although none are as important to outcome as completeness of the epileptogenic zone resection.

72 Temporal Lobe Epilepsy

Jeffrey Ojemann

Epilepsy is defined as recurrent, unprovoked seizures and is present in up to 0.5 to 1% of the population.^{1,2} The incidence of epilepsy is age-dependent, with approximately 50 or so new pediatric cases diagnosed per 100,000 per year.²⁻⁵ In up to one-third of young patients, epilepsy becomes intractable,⁶ and the majority of seizures remain of unknown origin. Nevertheless, a significant portion of the seizures do have a temporal lobe onset, and these patients are candidates for surgical treatment with the resection of temporal lobe foci. Up to 10% of cases of new-onset childhood epilepsy may have lesions,⁷ many in the temporal lobe. Most temporal lobe seizures are of unclear etiology, although genetic syndromes have been described.⁸ This chapter focuses on the evaluation and surgical management of this population.

Temporal lobectomy is the only surgery with level 1 evidence to support its use⁹ in an adult population. There is no such equivalent study for children. The evidence is very strong to support that surgical outcomes are more favorable than the natural history,¹⁰⁻²³ and in fact, a randomized study in children would likely not be undertaken, given the strength of current data.²⁴

Most cases of epilepsy are treated successfully with medication. A single agent can control epilepsy in the majority of patients.^{5,25} However, once the first agent has failed, successive drugs or combinations of drugs have a rapidly diminishing rate of success. After two failed drugs, the chance of complete seizure freedom with any medical combination is poor.^{5,25} The rate of intractability in patients with lesions and new-onset seizures has been much higher than in patients without lesions.^{6,7,26} In fact, the majority of those presenting with lesions do ultimately have recurrent seizures when followed for many years. Thus, early surgery should be strongly considered for children with difficult-to-control seizures and a lesion congruent with other evaluations.

72.1 Temporal Lobe Seizures: Semiology and Electroencephalographic Findings

Most temporal lobe seizures are complex partial seizures.²⁷ The characteristic temporal lobe seizure semiology in adolescents may be similar to that in adults. Epigastric rising, ictal vomiting (especially on the nondominant side), and experiential feelings (déjà vu, an abnormal feeling of familiarity; jamais vu, a lack of familiarity with an item that should be familiar; other feelings of altered time or flow of time) may resemble adult semiology. Speech alterations are common postictally after seizures in the dominant temporal lobe. The memory of temporal lobe seizures and surrounding events can be impaired. The recollection of seizure frequency may be an underestimate, especially if caregivers are not always present to witness any seizures.

In infants and young children, the semiology may be quite different. Hypomotor, motor, and epileptic spasms may all be seen.^{2,28,29} Dystonic posturing begins to be seen in young children.² Apnea can be the presenting form of temporal lobe epilepsy in the very young.^{30,31}

72.2 Natural History

Before the widespread use of surgical intervention, the natural history of poorly treated temporal lobe epilepsy was documented.^{32,33} Ongoing seizures can lead to a poor neurocognitive, behavioral, and psychosocial outcome.³⁴ A lack of seizure freedom, unemployment, and dependence, all contributing to social isolation, are common long-term findings.

The negative impact on cognitive function can be multifactorial. All antiepileptic drugs have side effects and, even at therapeutic levels, can adversely affect cognitive and behavioral function in children.³⁵ Even newer drugs, which may be better tolerated, have clear side effects. Levetiracetam is associated with behavioral disturbances and topiramate with language deficits, for example. Seizures may exist in association (causal or otherwise) with an underlying brain disorder. These disorders may primarily drive cognitive dysfunction. Lower measures of intelligence³⁶ and behavioral, schooling, and learning difficulties^{33,37} are all seen in this population, with adverse effects on quality of life.³⁸

Mortality is increased in children with uncontrolled epilepsy,³⁹ although the underlying neurologic disorder may contribute significantly to this finding.²

72.3 Evaluation

Diagnostic electroencephalography (EEG) is typically performed in the evaluation of children suspected to have epilepsy. Routine EEG can be normal in up to 50% of patients with epilepsy⁴⁰ thus, a single negative study does not exclude the diagnosis. Similarly, in a patient who clearly has temporal lobe epilepsy, a routine EEG may be normal, especially if the seizures are rare. However, a longer-term EEG, such as video EEG, which captures longer periods of time and ideally specific events, is typically sought as part of the evaluation. In temporal lobe epilepsy, anterior temporal interictal discharges are common. In fact, the absence of interictal discharges calls into question the diagnosis of medial temporal lobe seizures. The presence of lateralized interictal spikes is quite significant in the localization of seizures to one temporal lobe.

Auras may not have EEG changes, but full seizures would be expected to show EEG changes. Typical changes may include anterior temporal lobe spike-wave complexes, focal temporal lobe slowing, and temporal intermittent rhythmic delta activity (TIRDA). These may have a tendency in younger children to appear less focal.² Ictal recordings may rapidly spread and appear bilateral or even generalized.²

Magnetic resonance (MR) imaging arguably provides the most important piece of information in determining candidacy for temporal lobectomy.⁴¹ As in adults, hippocampal signal change, including hippocampal sclerosis, may be identified (► Fig. 72.1). However, the findings may be more subtle than in adults, and MR imaging findings may be absent in many cases, even cases of histologically proven sclerosis.¹⁴ More importantly, other pathologies are prevalent in pediatric series, including dysplasia of the hippocampus, parahippocampus, and/

or anterior temporal cortex. The concept of dual pathology is critical to pediatric epilepsy surgery. The presence of *both* a neocortical *and* a medial temporal lobe pathology is well described (► Fig. 72.2).^{15,42–45} Although the exact mechanism is

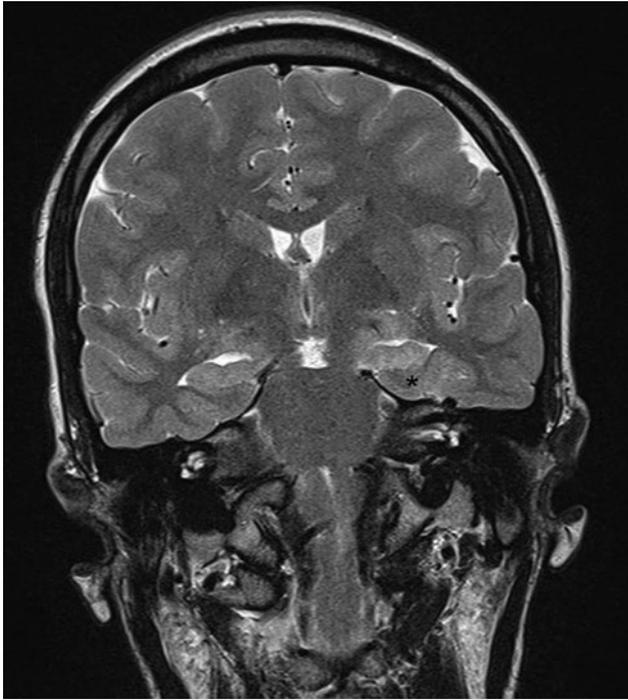

Fig. 72.1 Coronal T2-weighted magnetic resonance image showing left hippocampal sclerosis in a 3-year-old. The hippocampus (*) is small, with increased signal and absence of the internal architecture (see the dentate gyrus on the normal, right side).

unknown, the development of hippocampal pathology is presumed to be secondary to the primary lesion, becoming a second focus. Alternatively, the medial temporal changes can be part of the same underlying process(es), especially in the case of abnormalities (e.g., dysplasia) of the adjacent temporal lobe neocortex (► Fig. 72.3).

As in adults, MR imaging signal changes on the T2 and FLAIR (fluid-attenuated inversion recovery) sequences can help establish the diagnosis. However, volume loss may be less common. In fact, a dysplastic hippocampus can look thickened on coronal imaging, along with a fattened amygdala. Loss of the internal architecture of the hippocampus is seen in many cases, including those in which the hippocampus does not have volume loss (► Fig. 72.4). Other subtleties, such as abnormal organization of the basal temporal gyri,⁴⁶ may be best seen on three-dimensional reconstructions, some of which are not part of widely available imaging software packages. However, hippocampal sclerosis may be difficult to detect, and MR imaging may be normal in up to one-half of cases.¹⁴ Nevertheless, surgery for patients with negative MR results may still be successful.⁴⁷

Other MR imaging findings that can argue for epilepsy surgery are medial or lateral temporal lobe tumors⁴⁸ (► Fig. 72.5). These are typically low-grade tumors, such as gangliogliomas, dysembryoplastic neuroepithelial tumors (DNETs), or pilocytic tumors; however, malignant tumors, especially supratentorial primitive neuroectodermal tumors (PNETs), can present with seizures in the medial temporal lobe.

In the case of tumors, it may be advisable to proceed with surgery for oncologic reasons as well as for epilepsy control.⁴⁹ Although a benign-appearing lesion may not grow for some time, the epileptogenic nature of such a lesion can be established much more quickly than in nonlesional cases.²⁶ Given the frequent progression to intractability and the better prognosis

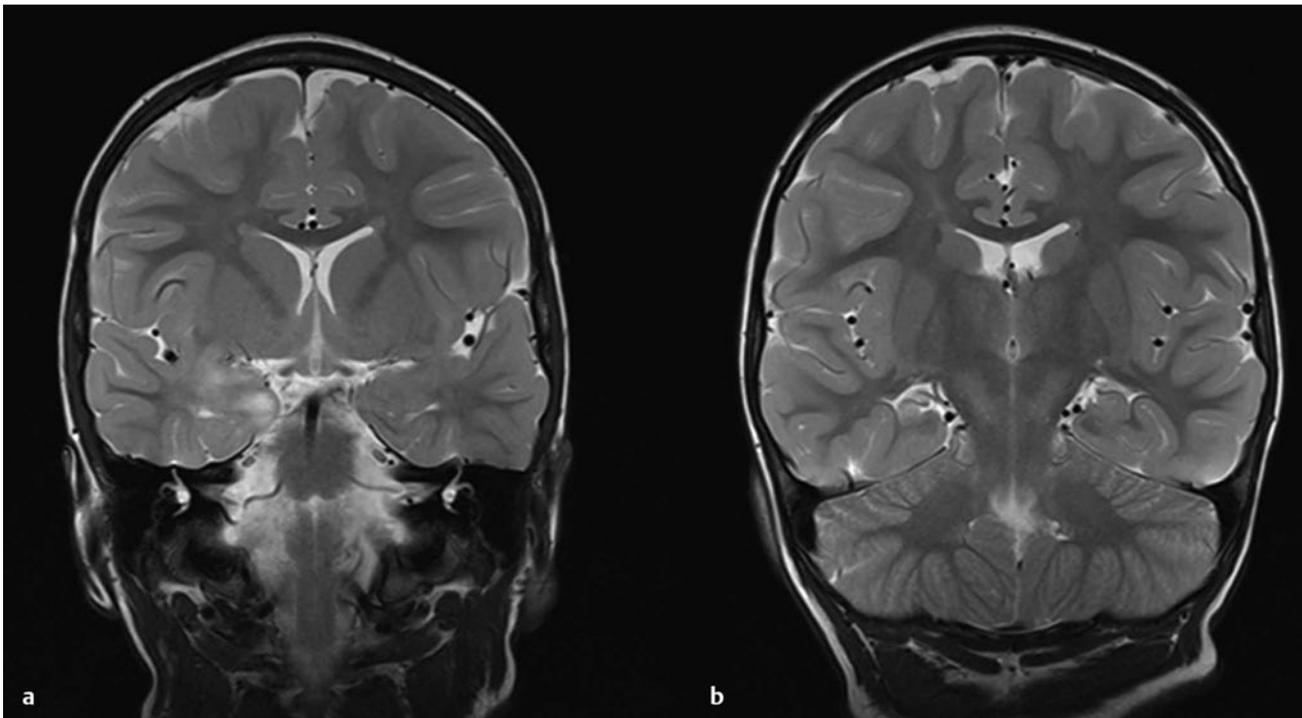

Fig. 72.2 (a) Lesion of the amygdala. (b) Hippocampal sclerosis co-presenting with the lesion in (a).

with surgery, resection of a tumor is typically indicated, just as a headache-causing tumor, even if likely benign, would typically be removed. Furthermore, resection allows a more accurate diagnosis by limiting the risk for undersampling. In the case of more aggressive lesions (► Fig. 72.6), early diagnosis and gross total resection may increase survival.

In the case of normal MR imaging findings or of EEG and MR imaging data that are not congruent, other imaging modalities may be employed.⁵⁰ Positron emission tomography (PET) with fluorodeoxyglucose (FDG) allows an assessment of the metabolic status of the cortex and can reveal temporal lobe foci.^{51,52} Epileptic foci are typically hypometabolic during the interictal phase (► Fig. 72.7). After a morning fast, radioactively la-

beled FDG is injected over 45 minutes. Cortical uptake allows measurement of the regional glucose metabolism. The period during injection should be quiet, without sensory stimulation or significant spontaneous movement; otherwise, those parts of the brain involved in, say, vision, somatosensory experience, or movement will show increased activation. During seizures, or even frequent interictal discharges, the local regional metabolism may increase. This can give a mixed picture, and the interpretation is often helped by recording the EEG during the PET to assess the interictal versus the ictal state.

Typically, the interpretation is made by comparing the two hemispheres and commenting on relative hypometabolism on one side. Statistical parametric maps can compare glucose metabolism (normalized to overall brain metabolism) with a database of PET scans from persons without epilepsy. This may better identify foci. The lack of large databases of pediatric PET scans has limited this approach, however.

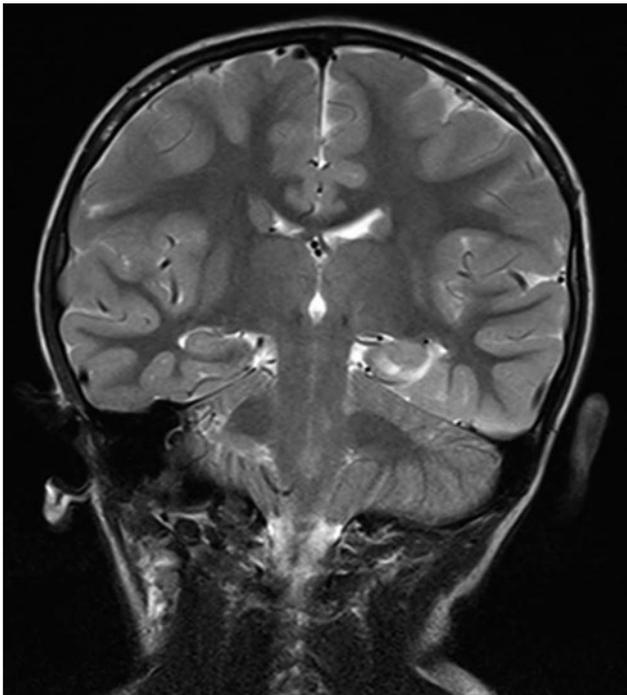

Fig. 72.3 Dysplastic lesion involving the parahippocampus and hippocampus on the left side.

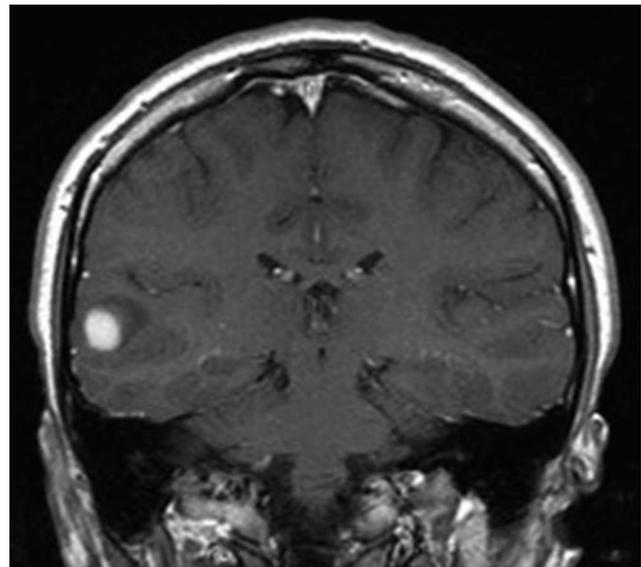

Fig. 72.5 Lateral temporal lobe lesion presenting with epilepsy. Resection showed a pilocytic astrocytoma.

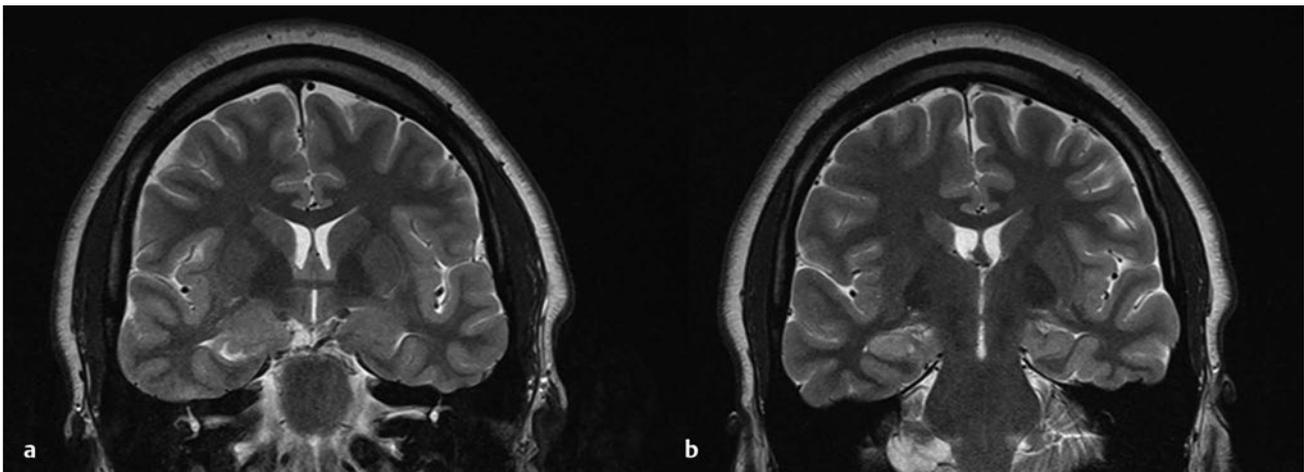

Fig. 72.4 (a) Anterior hippocampus and amygdala showing dysplastic lesion. (b) Extension of the abnormality into the hippocampus, with thickening of the hippocampus and loss of normal internal architecture.

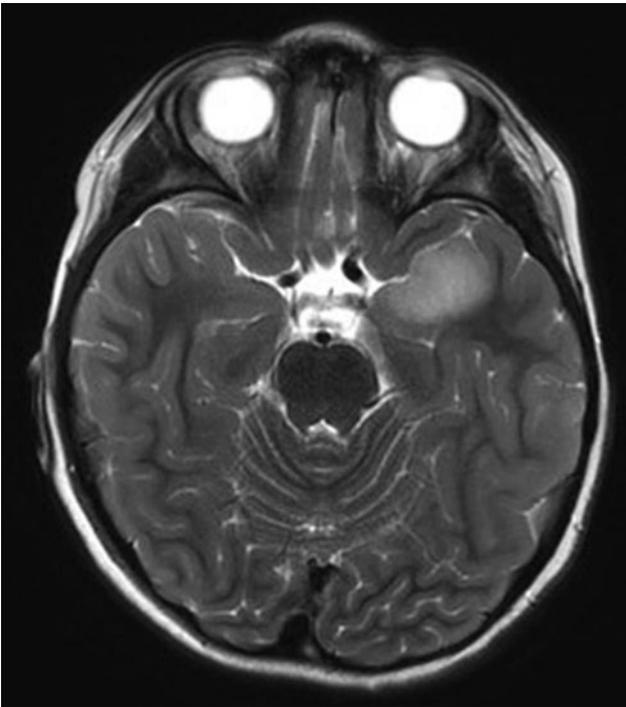

Fig. 72.6 Axial T2-weighted magnetic resonance image. Although it was not enhancing and presented with some hippocampal signal change, the lesion was malignant, a primitive neuroectodermal tumor.

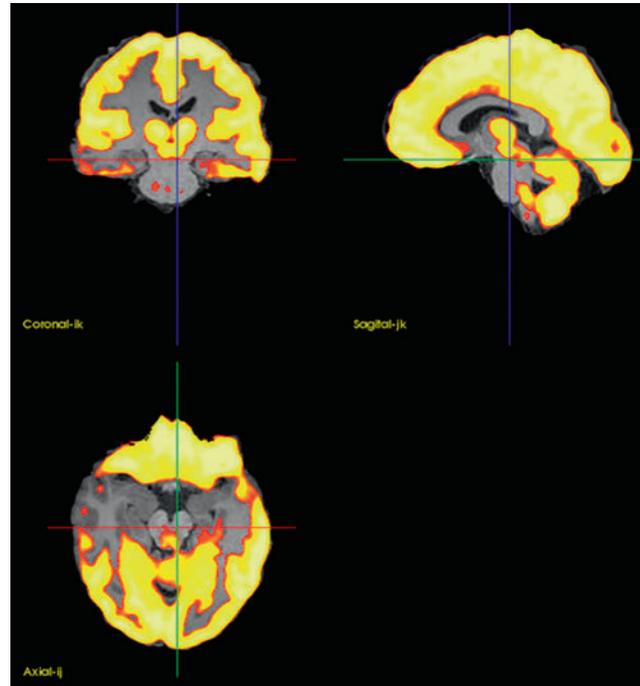

Fig. 72.7 The medial temporal hypometabolism on the positron emission tomographic (PET) scan (color scale) is superimposed on the magnetic resonance image. This co-registration aids in localization of the abnormality.

Single photon emission tomography (SPECT) studies⁵³ are obtained by injecting during the beginning of a seizure and during the interictal phase. This is typically done on the telemetry floor, so that the onset of a seizure can be determined both by the early clinical manifestations and/or by early changes in the EEG if it is being monitored by a knowledgeable technician. Then, the injection must be performed quickly to maintain the ability to obtain a valid localization. Because the logistical requirements (e.g., radiation handling, need for an EEG technician, qualifications of the technician, bedside nursing needs) are significant, these studies are done mostly at larger centers and/or are reserved for more challenging localization situations.

Subtraction of the ictal and interictal studies can show the blood flow change associated with seizure onset. The onset zone will show increased blood flow relative to the interictal baseline. The method is quite sensitive to late injection, early spread, and other factors that may lead to incorrect localization.

Other modalities that are employed less often⁵⁰ include magnetoencephalography (MEG), high-density EEG, and MR spectroscopy. MEG measures the magnetic field of brain activity and may help localize temporal lobe interictal activity.⁵⁴⁻⁵⁶ Movement is poorly tolerated, and primarily interictal studies are recorded. High-density EEG involves the placement of up to 256 electrodes to improve spatial sampling and may provide additional information.⁵⁷ Other sophisticated EEG mapping tools hold promise in increasing localization power.⁵⁸ Other MR imaging methods, such as MR spectroscopy, which looks at the chemical composition of the temporal lobe,⁵⁹ and functional connectivity MR imaging,⁶⁰ which looks at cross-region interactions, are emerging technologies that show promise in the diagnosis of temporal lobe epilepsy.

The extent of resection, and certainly the preoperative consultation, will be influenced by whether surgery is to be performed on the dominant or nondominant temporal lobe. Dominance is typically in reference to language function. Historically, dominance was established by the cerebral Amytal (or Wada) test. In this test, each hemisphere is independently injected. A short-acting anesthetic, such as amobarbital (Amytal; Marathon Pharmaceuticals, Deerfield, IL) or an alternative, is administered through a selective carotid artery injection. The injected hemisphere is temporarily disabled. Injection into the dominant hemisphere characteristically leads to the inability to speak. Memory dominance is indicated by the inability to remember items presented during the hemispheric anesthesia.⁶¹ The test is limited by the distribution of anesthetic, which does not well cover the hippocampus or posterior-medial temporal lobe, although it does cover frontal as well as temporal areas. Left dominance is extremely common in right-handed individuals with a normal developmental history.⁶² Functional MR imaging has increasingly been used as an alternative mechanism to establish dominance.⁶³⁻⁶⁵ Furthermore, it is suspected that children can better tolerate resection of the dominant temporal lobe; however, the evidence for this is minimal, and verbal memory deficits can be seen,⁶⁶ as in adults.⁶⁷ Functional MR imaging (and the Wada test) require a cooperative patient and can, by a person with significant training, be done in children as young as 5 years of age.^{68,69}

Surgical resection is often guided both by the preoperative evaluation, including imaging, and also by direct brain recordings, or electrocorticography (ECoG). ECoG can be acquired intraoperatively⁷⁰⁻⁷³ or over longer periods by implanting electrodes for several days.⁷⁴ The latter approach is used when diagnostic localization is unclear despite noninvasive tests (► Fig. 72.8). Typically,

Fig. 72.8 Dual pathology on invasive monitoring. Independent interictal discharges are seen in basal temporal electrodes (rows RAT3, RAT4, and RAT5 [*]) and in medial temporal structures (RMT1 [†]).

the questions relate to the extent of medial versus lateral involvement in temporal lobe epilepsy (beyond what can be addressed in a standard resection), the evaluation of orbitofrontal and/or insular involvement, the inclusion of the temporal lobe in a case in which multiple regions may be involved based on evaluation, and the localization of function (e.g., speech) before a resection.⁷⁵

Intraoperative ECoG⁷⁶ is limited by the length of recording and is typically interictal, although a seizure may be fortuitously recorded, especially in an active case. There is no standard for duration, and the required length of time of recording may vary depending on the question at hand. If ECoG is being used to limit a resection, say, of the hippocampus,^{70,77} then frequent interictal activity in just a few minutes is sufficient to exclude the null hypothesis⁷⁸ and therefore justify resection of the involved area (provided the area was suspected to some degree ahead of surgery). The use of intraoperative ECoG to augment lesionectomy is a common strategy in temporal lobe surgery,⁷⁹ both to ensure adequate neocortical resection⁷⁹ and also to assess the role of the inclusion of medial temporal (e.g., hippocampal) structures. This approach is supported by meta-analyses that suggest superior outcomes⁸⁰ and other comparison studies,⁸¹ but a direct comparison has not been done, and lesionectomy alone may be a successful strategy in some cases.^{82,83} Intraoperative ECoG can be influenced by anesthetics⁸⁴ propofol (Diprivan; Pfizer, New York, NY), dexmedetomidine,⁸⁵ and sevoflurane are typically used, although minimization of anesthesia as tolerated during actual recordings may be indicated.

Implanted ECoG may use subdural grid and strip electrodes, depth electrodes, foramen ovale electrodes, or a combination of some or all of these configurations.^{74,86,87} Medial temporal lobe coverage should include the hippocampal and parahippocampal regions.⁸⁸ Electrode leads are tunneled through the scalp after the dura is closed and the bone flap reapproximated. Alternatives for closure include loose reapproximation of the bone flap, use of an osteoplastic flap, and sterile storage of the bone flap until removal of the electrodes and resection, as indicated by the results of the monitoring. Electrode placement is generally well tolerated but does carry a higher risk for infection compared with other surgeries, and neurological deficits, especially transient, can occur.^{89–91}

72.4 Surgical Approach: Lesionectomy

When a lesion has a benign appearance, such as of dysplasia, a cavernoma, or a hamartomatous lesion (e.g., DNET), then the

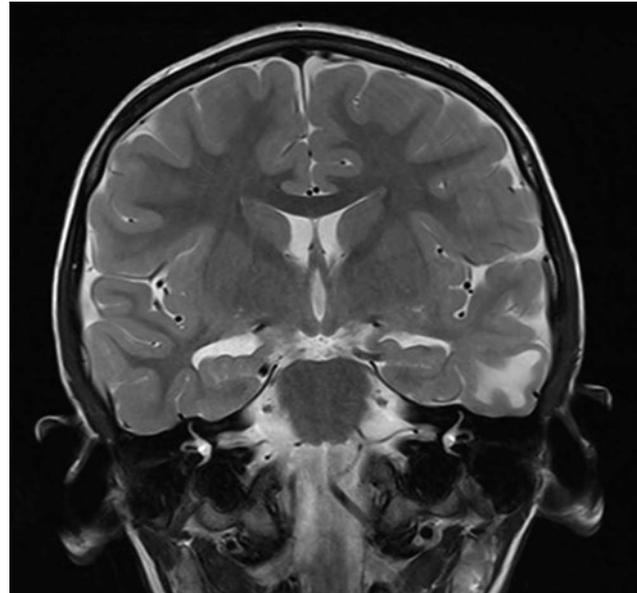

Fig. 72.9 Type IIB dysplasia of the lateral temporal lobe. The medial structures were spared, with seizure freedom on long-term follow-up.

decision to operate is usually driven by seizure control. EEG evidence of congruent interictal or ictal activity further supports surgery, but the absence of EEG abnormalities should not preclude surgery if other aspects of the evaluation (e.g., seizure type, neuropsychology) are congruent with the MR imaging appearance of the lesion. As discussed above, there is weak evidence to support the use of ECoG to enhance seizure resection. This is particularly true when adjacent structures are suspected, as in the case of hippocampal involvement in anterior–medial tumors.

The surgical steps of temporal lobe lesionectomy depend on whether the target is medial, lateral, or some combination thereof. Lateral lesions (► Fig. 72.9) are readily approached through a standard craniotomy. For many lesions, neuronavigation will be helpful in planning the incision and bone flap. Epidural hemostasis is achieved and a dural opening made in the usual fashion. Normal end-tidal CO₂ along with attention to head positioning is usually adequate. Cerebrospinal fluid aspiration can be used to achieve brain relaxation without the need for diuretics or hypoventilation. Elevation of the head is also unnecessary and increases the risk for air embolus. Steroids may be considered before surgery and may aid recovery.

Navigation may be especially important in cases of intrinsic brain tumors that may have a visual appearance similar to that

of normal cortex. Dysplastic tissue may be firm to gentle palpation and will aspirate differently from surrounding cortex; it often has a foamy appearance when the ultrasonic aspirator is used on lower settings. Dysplasia is particularly common in association with mesial temporal lobe pathology,^{42,45} although in an adult series, anterior gray-white abnormalities did not have to be completely resected.⁹² If EcoG is performed before lesion removal, the extent of resection can be planned.

Functional considerations often determine the practical limit of resection. Tissue that is disconnected or can be undermined by resection into the white matter of the temporal lobe need not be spared. However, resection into speech areas will increase morbidity. As discussed before, language dominance may be determined with cerebral amobarbital or imaging, but language dominance is often inferred by side and clinical presentation. Many dominant temporal lesions are well anterior and/or medial to suspected speech areas. However, for more lateral and posterior lesions, speech mapping may be necessary if the boundaries of a lesion are not distinct or approach language areas. Speech mapping can be performed with an awake surgery even in a preadolescent patient,⁸⁵ or invasive monitoring can be performed to determine language localization before a definitive resection. Speech may be different in children, with temporal lobe sites less common in one series.⁶³

On the nondominant side, resections of the lateral surface are not reliably associated with clinically obvious deficits. Thus, a major consideration is extensive resection of the basal temporal lobe that could lead posteriorly to impairments of face processing, although the anatomical correlation with clinically relevant deficits remains unclear. Visual field deficits will be limited to quadrantanopsia unless the resection is taken so far back that inferior field fibers are injured where they come out of the geniculate. Of note, these fibers can be injured with a far posterior-lateral temporal resection. The vascular supply coming off the depth of a lateral temporal-occipital sulcus can be a tenuous supply to geniculocalcarine radiations, and hemianopsia following posterior-lateral temporal resection can be seen.

Once the extent of resection is determined, the corticectomy can begin with coagulation of the pia. Dividing the pia sharply allows ultrasonic aspiration of the lesion. Many lesions will respect adjacent sulci, and the subpial approach⁹³ allows a nice delineation of the resection boundaries. If gyral vessels are inadequately coagulated, they may retract, and coagulation of the cut pial edge and deeper coagulation when a sulcus is approached is usually sufficient. The operative microscope aids in discerning lesion margins and preserving the tissue and vascularity of surrounding brain.

For lesions that are less superficial, the temporal horn of the lateral ventricle provides a critical landmark to avoid extension of the resection through the temporal stem or into the subcortical structures. Inferior and anterior to the ventricle, the medial pia is a reliable boundary between major vascular structures, the brainstem, and cranial nerves. Some pathologies will cause the pia-tissue interface to be more adherent; however, the plane can usually be identified at the edge of the tentorium and followed medially.

Above the ventricle, no such barrier exists, and resection must not violate the basal ganglia or perforators from the middle cerebral artery. Thus, for deeper lesions, identification of the lateral horn should be an early step. By taking the resection

anteriorly and inferiorly first, and then resecting superiorly and posteriorly at the same depth, it is guaranteed that one will enter the ventricle before violating the temporal stem. If the superior and posterior resections of temporal cortex are not kept as superficial as the anterior and inferior extent, this relationship is lost, and other means of keeping the resection safe will be required.

72.4.1 Medial Resections

The appropriate extent of surgery and the approach to medial regions are controversial.⁹⁴⁻⁹⁶ So-called "selective" approaches advocate minimal resection of the lateral cortex, "standard" temporal lobectomy with aggressive resection of the lateral temporal lobe cortex (classically 4 cm on the dominant side and 6 cm on the nondominant side), and "tailoring" with EcoG and sometimes functional (speech) considerations to determine the lateral extent. Although in adults selective procedures seem to be adequate,⁹⁷ several studies suggest that a highly selective approach in children will miss significant temporal lobe pathologies and should be used with caution.^{98,99}

The entry to the ventricle is the key first step in approaching medial temporal structures. Of the myriad of so-called selective approaches, all but the transylvian approach¹⁰⁰ require entry into the ventricle as part of the resection before removal of the medial temporal lobe. A standard temporal lobectomy involving resection of the lateral cortex can be limited to the middle temporal gyrus, often as little as 3 cm, and can be tailored based on the presence or absence of recorded epileptiform activity by EcoG or imaging or on other concerns for anterolateral temporal involvement. Because the ventricle typically sits under the superior temporal sulcus, extensive resection of the superior temporal gyrus is usually unnecessary solely for the purpose of reaching the ventricle. An approach through the middle temporal gyrus or through the inferior temporal gyrus or upward retraction and resection of the fusiform gyrus,¹⁰¹ will allow an approach to the ventricular wall. A more posterior approach can also be used.¹⁰² Once the ventricle is entered, the lateral amygdala, choroid, and hippocampus are typically visible, even in the setting of mass lesions. The ventricular wall can be opened along the extent of its exposure. Early in the process, a cotton patty can be placed in the ventricle to avoid bleeding into the remainder of the ventricular system. Additional EcoG can now be performed directly on the hippocampus. The lateral amygdala can be resected flush with the roof of the ventricle; however, there is no pia to provide a superior border. The mesial pia will be encountered from any of several maneuvers—resection of the lateral amygdala, superior extension of the resection of the basal temporal lobe, resection of the temporal lobe off the sylvian fissure anterior to the ventricle, and resection of the hippocampus anteriorly off the choroidal fissure. The order of these steps is arbitrary and can be modified according to the surgeon's preference.

If the superior temporal gyrus anterior to the ventricle is removed early in the resection, the sylvian fissure can be followed laterally to medially. With the use of operative microscopy, the resection is taken anteriorly to the middle cerebral artery, which can often be seen through the intact pia. As the resection is taken in the inferomedial direction, the mesial pia will be encountered. The lateral amygdala resection can be completed here as the most medial part is taken off the pia. At this point,

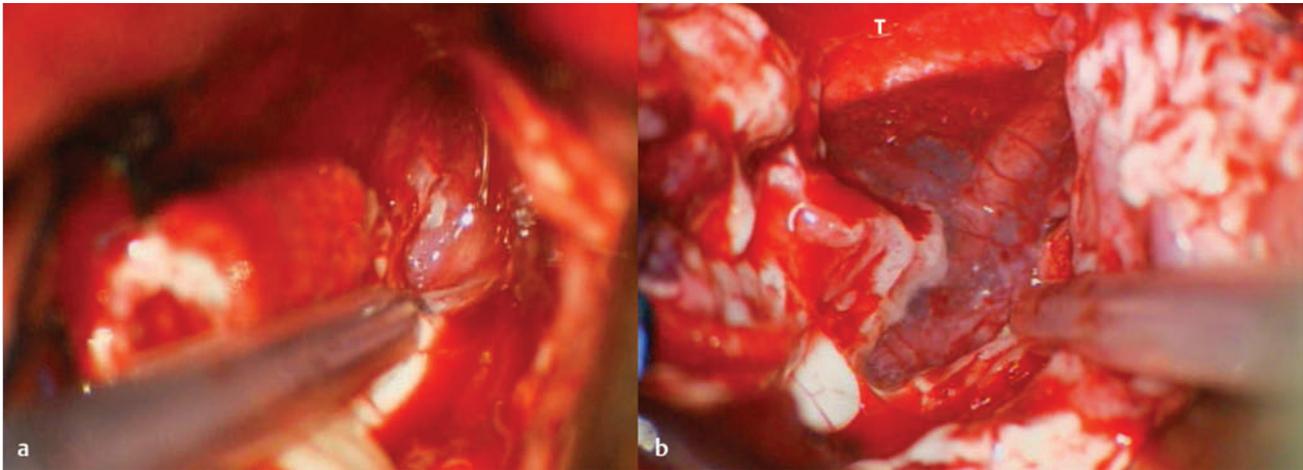

Fig. 72.10 Mesial subpial resection during a left temporal lobectomy. (a) Just medial to the head of the hippocampus is the intact pia, with neurovascular structures evident underneath. (b) After resection of the tissue off the pia with the ultrasonic aspirator, the third nerve, carotid artery, choroidal artery, and branches are all protected. T, tentorial edge.

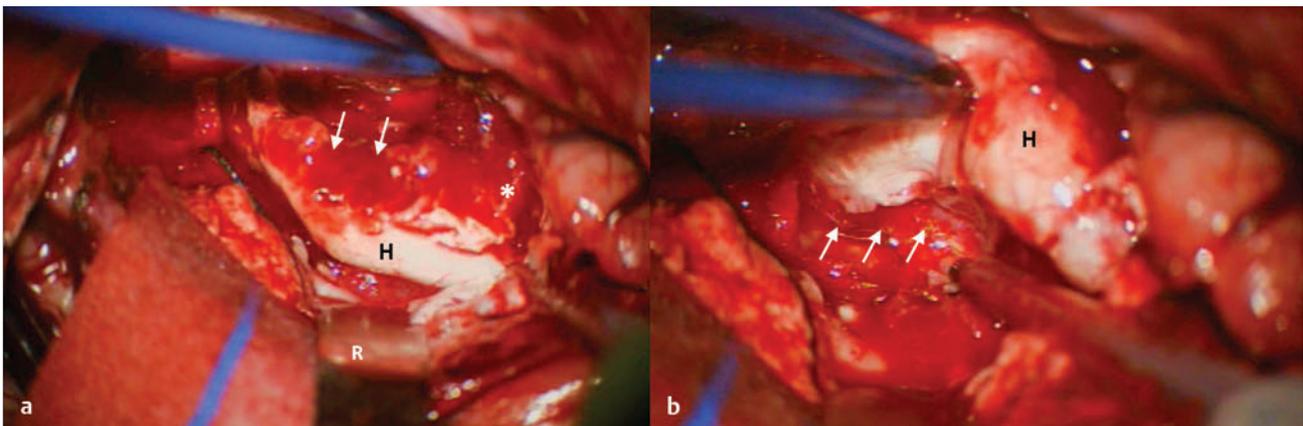

Fig. 72.11 During the medial part of the temporal lobectomy, the hippocampus is skeletonized from inferiorly (a) and along the medial aspect (b). (a) The residual lateral temporal cortex (*) is seen in this right temporal lobectomy. The orientation is surgical—anterior is to the left of the image, inferior to the top. The hippocampus (H) is within the exposed temporal horn. The retractor (R) is placed on the remaining superior temporal gyrus, just superficial to the roof of the ventricle. Arrows indicate the edge of the basal temporal resection at this point. (b) The fimbria of the hippocampus (H) is disconnected from the choroidal fissure (arrows).

the hippocampal head will remain. By looking at the choroidal point, the most anterior portion of the temporal horn, the remainder of the hippocampal head can be seen. Tissue can be taken off the choroidal fissure, starting anterior to the choroid plexus. The tissue is very thin, and only a small amount needs to be aspirated off the fissure. As the resection moves anteriorly and sharply medially, it is taken in front of the midbrain and the medial pia is encountered. The third nerve often will be visible, along with the carotid artery and posterior communicating artery, through the pia (► Fig. 72.10). Coagulation of the mesial pia is rarely necessary, and simple application of a cotton patty is usually sufficient to stop the venous bleeding. This also avoids any coagulation injury to perforators off the carotid or posterior communicating artery that may be just under the mesial pia.

Posteriorly, the choroidal fissure is further exposed. A self-retaining retractor may be used to further expose the temporal horn. Retraction that is too deep or too posterior should be

avoided to prevent injury of the lateral geniculate. Cortical retraction also should avoid injury to adjacent cortex, where, especially on the dominant side, critical regions may be close to the original cortical resection. The fimbria is then resected off the choroidal fissure posteriorly (► Fig. 72.11a). This will be very thin and may have venous bleeding that can be controlled with gentle tamponade, and resection will immediately show the brainstem on the other side of the pia. Posteriorly, the hippocampus will thin, and by 3 cm or so from the head, it will begin to merge with the cingulum and will no longer be along the medial pial surface. The posterior extent can be determined by these anatomical features, along with preoperative MR imaging (e.g., of sclerosis) and presurgical ECoG. The posterior extent is then made with a resection perpendicular to the choroidal fissure that joins the inferior temporal resection with the choroidal resection. Inferolaterally, the hippocampus is freed from the remaining lateral cortex (► Fig. 72.11b). The hippocampus can

now either be resected piecemeal or rolled off the hippocampal sulcus, with ultrasonic aspiration of any adherent areas during the process.

Any remaining hippocampal tissue can be removed with the ultrasonic aspirator, although posteriorly, the medial parahippocampus need not be followed posterior to the quadrigeminal cistern, which sits just behind the typical extent of an aggressive hippocampal removal. Although ECoG may not be useful after lateral resections,⁷¹ the outcome in temporal lobe surgery may be better if any residual hippocampus is devoid of ECoG abnormalities.⁷⁰

Hemostasis is achieved by a combination of lining the cavity with Surgical (Ethicon, Somerville, NJ), temporarily applying Gelfoam (Ethicon), and/or tamponading the area with cotton patties. Final hemostasis is verified with the Valsalva maneuver, and dural closure follows along with bone fixation and layered closure of the scalp.

72.4.2 Nonlesional Cases

When the results of MR imaging are negative, or the findings are subtle and/or incongruent with other parts of the evaluation, the anatomical limits are less obvious. The integration of all of the components of the evaluation is particularly important in these situations. If all the evidence points to temporal lobe dysfunction, then a standard temporal lobectomy may be appropriate. This can be confirmed and tailored with ECoG, especially in the hippocampus, where the resection of all interictal abnormalities may be associated with a better outcome.^{70,78} The aggressive approach to interictal abnormalities must be balanced with other data indicating that it is not necessary (or perhaps possible) to leave the patient with a completely normal ECoG. Especially after resection, residual activity may not be relevant to outcome,⁷¹ especially if distant.¹⁰³

If the evidence suggests temporal lobe involvement, the resection of lateral and medial structures is fairly standardized. The superior and middle temporal gyri can be spared while basal and medial structures are resected; thus, it is reasonable to attempt to discern whether these structures are involved. On the other hand, the anterior 2 cm of the basal temporal lobe is likely to be removed in any approach. Surgery in this situation would, of course, avoid entry into the insula or the far posterior temporal lobe such that a full hemifield deficit would be expected. Rather, such regions would be resected only with definitive evidence of their involvement.

Frequently, “nonlesional” cases do have latent pathology. Nearly half of cases of hippocampal sclerosis in children have negative findings on MR imaging,¹⁴ and dysplasias can be quite subtle on MR imaging. In these cases, though, a highly selective approach would seem more likely to miss the pathology.

72.5 Outcome

72.5.1 Complications

Temporal lobectomy is frequently associated with a superior quadrantanopsia. The association of the temporal horn with the Meyer loop makes this a vulnerable track during any lateral approach to the ventricle, including selective corticectomy approaches.¹⁰⁴ The proximity of the midbrain, third and fourth

cranial nerves, and perforating vessels puts them at risk during temporal lobectomy, although the incidence of permanent injury appears to be low.¹⁰⁵ Memory deficits are typically side-specific, with verbal memory problems seen after left-sided surgery⁶⁶ more often than after right. However, preoperative memory and imaging abnormalities play a very strong predictive role, with both poor memory and lesional MR imaging findings resulting in a higher rate of new problems after surgery.⁶⁷ Whether these effects are mitigated by the younger age of pediatric patients undergoing temporal lobectomy is unproven but suspected based on the few series with careful long-term follow-up of surgical patients.^{106–108}

72.5.2 Seizures

Seizure control after temporal lobectomy is superior to that achieved with medical management in adults. This statement is based on level 1 evidence from a randomized clinical trial of surgery versus medical management⁹ and remains the strongest available statement in epilepsy surgery. It is hard to imagine a similar study being undertaken in children because the randomization process was done after the decision for surgery had been made. The seizure-free outcomes for pediatric temporal lobectomy are quite good based on retrospective studies, and the implications for delaying such a good outcome for a year of study are significant.

Lesionectomy would be expected to have a strong short-term outcome, with many series showing seizure freedom in up to 70% of patients at 3- to 5-year follow-up.^{10,14,21} Mesial sclerosis also has a good outcome, along with observable focal cortical dysplasias. Type I dysplasia and nonspecific pathologies do less well, perhaps because of the more diffuse nature of the disease and the (not independent) challenge of defining surgical margins in the absence of a focal lesion. For all types, outcome studies suggest that complete seizure freedom in long-term follow-up is much more elusive than in short-term follow-up. In 15-year follow-up reports of adult temporal lobectomy, rates are well below 50%. Even the 1-year follow-up in Weibe’s study showed only a 50% rate of complete seizure freedom within the year, and only one-third of patients were free of auras. Thus, retrospective and short-term follow-up reports of outcome should be treated with significant skepticism regarding the longevity of results.

72.6 Other Treatments

Attempts to treat temporal lobe epilepsy directly have also been made with Gamma Knife radiosurgery, even in children.¹⁰⁹ Direct thermal ablation with interstitial laser therapy is another intriguing new application,¹¹⁰ although it has not yet undergone extensive clinical testing.

72.6.1 Outcome

Corresponding brain disorders that may be present must be considered in any discussion of the effect of surgery on cognitive development. Surgery removes tissue, and this risk must be balanced with the other factors mentioned. Studies have shown the benefit of surgery,^{111,112} but also that surgery, especially on the dominant side, may be associated with lingering

deficits.^{66,113} The natural history of uncontrolled seizures is poor with regard to intellectual development.¹¹⁴ Certainly, in catastrophic cases, surgery provides clear benefit when successful in seizure control.¹¹⁵ Many of these deficits remain despite successful surgery, including difficulties with learning¹¹⁶ and language development.¹¹⁷ Nevertheless, the studies of long-term intellectual outcome appear to strongly favor surgical intervention overall.¹¹⁸

Neurocognitive problems like anxiety and depression have a strong association with epilepsy and with the stressors of surgery. These problems may not follow the same course as epilepsy postoperatively. Thus, problems like depression must be addressed after surgery, even in the seizure-free patient.¹¹⁹ Quality of life improves after temporal lobectomy, and the psychosocial benefits may be better with earlier intervention, although many psychosocial problems persist even with surgical control.^{120,121} Complete seizure freedom is consistently associated with improved quality of life,¹²² and some studies have shown an improvement in quality of life even with significant, although incomplete, seizure control.^{120,123}

Although the baseline risk for sudden death with epilepsy (SUDEP) may be lower in children,¹²⁴ with mortality driven primarily by associated neurologic conditions, it is still elevated,⁶ and it is compelling that the risk for SUDEP is less following successful epilepsy surgery.¹²⁵ Epilepsy surgery is associated with an estimable improvement in life expectancy¹²⁶ and is cost-effective compared with ongoing medical treatment.¹²⁷ Drugs may not be able to be discontinued completely in many cases.¹²⁸ Despite the efficacy of surgery, access is variable and relies on both patient and provider factors.^{129,130}

Pearls

- Temporal lobe epilepsy is a common form of focal epilepsy in children.
- Intractability can be defined as the failure of two attempted medications. It is much more likely to occur in the face of a lesion.
- Surgery for temporal lobe epilepsy is supported by level 1 evidence of efficacy in adults and by abundant level 3 evidence of efficacy in children.
- Dual pathology, with both a neocortical and a mesial temporal focus, is more common in children.
- Improvement in quality of life depends on postoperative seizure control.
- The cognitive outcome after temporal lobectomy is less clear and likely multifactorial.

73 Extratemporal Epilepsy Surgery

Matthew D. Smyth and Timothy W. Vogel

Surgical procedures for extratemporal lobe epilepsy (ETLE) have been built on the success of temporal lobe resections. In 1990, the National Institutes of Health adopted surgical resection as an alternative treatment to medication-resistant epilepsy in children.¹ Temporal lobe resection, described in Chapter 72, has demonstrated significant success in reducing seizures in selected children.² A randomized controlled trial for temporal lobe epilepsy revealed improved seizure freedom for patients with surgical intervention versus medical therapy.³ Although it might appear that outcomes after ETLE surgery could approximate those seen after temporal lobe resections, a wide range of pathologies, diagnostic evaluations, and surgical approaches contributes to substantial variability in the outcomes of ETLE surgery.

Extratemporal pathologies account for a substantial majority of cases of ETLE in children, whereas in adults, temporal lobe epilepsy predominates. However, children treated for ETLE may also have temporal lobe involvement as part of an underlying multilobar pathology. Typically, these extratemporal areas are the frontal, occipital, and/or parietal lobes, and eloquent cortex in these regions may be affected. ETLE also presents an additional degree of difficulty in localization because seizures can quickly propagate to additional locations throughout the cortex.

Extratemporal surgical approaches are employed to address a broad range of pathologies, from tumors to malformations of cortical development, vascular lesions, and other genetically inherited disorders.⁴ Each disease state has its own particular evolution, symptom onset, and management strategies, and multidisciplinary experience at a comprehensive pediatric epilepsy center is required to evaluate and treat affected children most effectively.

73.1 Neural Plasticity

The last several decades have seen significant improvement in the management of children with ETLE, and the field has enjoyed a shifting paradigm from one of watch and wait to one of earlier intervention that capitalizes on neural plasticity in the young child. Neural plasticity refers to the various mechanisms involved in the maturation of the developing cortex in children and the ability of the central nervous system (CNS) to respond to changes in its structure or function.⁵ Discoveries in the neuroscience community have fueled new data on neural plasticity and its impact on CNS development.⁶ Apoptosis, neurogenesis, synapse formation, and pruning all play a role in conferring a dynamic environment in the pediatric brain. Language dominance, for example, has been found to be set no earlier than 5 to 6 years of age.^{7,8} Neural plasticity plays a role in making possible a greater extent of surgical resection in eloquent cortex than would otherwise be permissible in adults.

There is evidence that persistent seizure activity limits the degree of neural plasticity in the developing brain and may impact a child's ability to achieve otherwise-anticipated neurocognitive outcomes.⁹ Although plasticity may allow the transfer of function from interhemispheric or intrahemispheric locations, neurocognitive development may be restricted to

suboptimal levels.⁵ In a consideration of the clinical assessment and treatment options for pediatric patients with extratemporal etiologies, possibly with syndromic manifestations, it is necessary to keep plasticity in mind because it may substantially influence surgical outcomes.¹⁰

73.2 Epidemiology: Incidence and Prevalence

An estimated 65 million people are affected by epilepsy worldwide. The incidence in developed countries is nearly 50 per 100,000, and the prevalence is 700 per 100,000.^{11,12} As recognition of the morbidity associated with epilepsy improves, the disease is increasingly being diagnosed and evaluated by pediatric epilepsy teams. It is estimated that recurrent seizures affect approximately 1% of children,¹ and these persistent seizures, if left untreated, are associated with long-term impairment in cognition, intelligence, and quality-of-life measures. It is estimated that 120,000 children in the United States will be evaluated each year for newly recognized seizures,¹³ and epilepsy will be diagnosed in as many as 45,000 of these cases. In addition, as many as 325,000 children ages 5 to 14 years have active epilepsy, and a majority of adults with epilepsy had a childhood onset.¹³ It is estimated that 100,000 to 200,000 patients in this country may be candidates for surgery because 10 to 20% of children with epilepsy meet the criteria for refractory epilepsy.^{14,15} Predictive factors for refractory epilepsy include early onset and an association with such syndromes as West syndrome, Lennox-Gastaut syndrome, and Ohtahara syndrome. More than 3,000 surgeries are performed each year in the United States for pediatric epilepsy, and with increasing recognition of the disease and the improving diagnostic tools available to surgeons and clinicians, this number is likely an underestimate.¹⁶

73.3 Medical Treatment and Definitions of Refractory

Before surgical management for ETLE is considered, otherwise treatable forms of epilepsy must be excluded.¹⁷ The first priority is to determine if adequate medication has been used to treat the epilepsy. Medication-refractory epilepsy is defined as epilepsy that persists or is unresponsive to two first-line antiepileptic drugs (AEDs).^{18,19} Despite optimal pharmacotherapy, the disease of 30% of the 65 million patients with epilepsy worldwide remains resistant to AEDs.²⁰ The selection of AEDs is individually tailored to each child and takes into account the child's developmental stage, the safety profile of the medication, and the presence of comorbidities. AEDs may affect cognitive and behavior functions, and their levels may be altered by other medications. Medications taken for comorbidities may lower the seizure threshold and impact AED selection.²¹ Children taking more than one AED to control their epilepsy are less likely to respond to additional medications, and once two or three medications have been attempted, benefit from pharmacotherapy is

unlikely.⁵ Other predictors of drug resistance include mixed seizure types, neonatal age at onset, abnormal neurologic examination, early seizure breakthrough after treatment with medication, and underlying structural abnormalities.¹⁸ In addition, some children are unable to tolerate the side effects of medical treatment, and this, too, may confer a pharmacoresistant status.

A ketogenic diet may be used to treat drug-resistant epilepsy in children. The ketogenic diet involves altering the ratio of fat intake to protein and carbohydrate intake. A ratio of 4 g of fat to every 1 g of carbohydrate and protein simulates the metabolic state of fasting and has been shown in a randomized controlled trial to significantly reduce more than 50% of seizures in selected pediatric patients.²² The ketogenic diet is the first line of treatment in epileptic disorders resulting from mutations in the genes for glucose transporter proteins and mutations that cause pyruvate dehydrogenase deficiency. The ketogenic diet is contraindicated in other metabolic disorders, such as those resulting from fatty acid oxidation or carnitine abnormalities.²³ Dietitians and pediatricians can determine when such diet restrictions are warranted.

Because some children who have epilepsy present with various syndromes, there may be additional risks and considerations that prevent surgical intervention. Cardiopulmonary and coagulation status and other comorbidities should not be excessive when surgical options are pursued. Finally, the results of a diagnostic work-up with various studies discussed in the following sections of this chapter should be concordant and implicate an epileptogenic region amenable to resection.

73.4 Common Semiologies by Lobe

The first step in identifying an epileptogenic zone for surgical resection is to use the information on seizure semiology to improve lateralization and localization.^{24,25} An assessment of semiology, or the observable manifestations of seizures, begins by combining historical information provided by the patient and family with video electroencephalographic (EEG) recordings. Descriptive terminology for seizure semiology has been introduced and is supported by the International League Against Epilepsy (ILAE) to improve the significance of localization and the recognition of semiologic features.²⁶ Studies in pediatric patients have helped to identify semiologies that are common to anatomical regions or structures based on EEG findings and that are eradicated following surgical resections. Although misleading in certain cases, semiologies often provide additional clinical information for localizing ictal onset.

Seizure semiologies may be difficult to detect in clonic, tonic-clonic, atonic, gelastic, and myoclonic seizures because they have a generalized onset and nonlocalizable features. These seizures may originate from subcortical regions, such as the thalamus, that generate synchronous activity with extensive ictal spread. A subset of generalized seizures may also have a focal onset that can be identified on EEG recordings, and definitive localization in these seizure types is difficult, so that additional diagnostic studies are warranted. There is also current debate about whether infantile spasms constitute a generalized or a focal seizure type.²⁴ Seizures that involve sustained lateral

deviation of the eye, head, or trunk from the midline are known as versive seizures and can indicate multilobar involvement.

The following semiologies refer to an anatomical location; however, one-to-one correlation is not necessarily the rule because there may be degrees of overlap with adjacent cortical regions. The semiology of seizures may evolve as a child ages, and these changes must be considered. As the myelination of white matter pathways evolves in the first decade of life, intrinsic pathways develop to inhibit seizure propagation, causing the seizure semiology to more closely resemble adult patterns.²⁷ Caution and confirmatory studies should be employed to identify concordant information for seizure localization.

73.4.1 Temporal Lobe Seizures

Seizures that lead to alterations in cognition, attention, memory, or other executive functions are often related to a temporal lobe origin. If the temporal lobe is involved unilaterally or bilaterally in seizure onset, there may be altered consciousness, verbal and nonverbal behavior, and postictal memory loss. In addition, temporal lobe seizures may present with various combinations of olfactory, gustatory, and pharyngeal auras. Auras may also originate from multilobar involvement. Other aura types, such as visual hallucinations, are associated with involvement of the parietal and/or occipital lobes. Finally, oral and upper extremity automatisms may also originate from the temporal lobe, whereas other automatisms, such as bicycling, may be related to frontal lobe pathology.

73.4.2 Frontal Lobe Seizures

Frontal lobe seizures are the most common ETL and account for approximately 20 to 30% of childhood epilepsies.²⁸ Frontal lobe seizures also comprise a significant portion (15 to 30%) of medication-resistant epilepsies. Seizures in the frontal lobe have far-reaching effects and may manifest with a host of possible deficits in children. Children who have frontal lobe epilepsy present with impaired motor and executive function and with socialization, behavior, speech and language, and cognition problems. Behavioral dysfunction manifests as disinhibition, aggression, or attention disorders. Additionally, when children who have frontal lobe epilepsy are compared with patients who have temporal lobe–based or absence seizures, the children with frontal lobe ictal zones have more difficulty with perceptual organization, self-regulation of behavior, impulse control, visual and auditory attention, and visual working memory.²⁹

Frontal lobe seizures present with variable semiologies that include hypermotor activity with repetitive movements in the upper extremities and can be associated with loss of consciousness. Hypermotor activity in children is also a prominent component of seizures originating in the temporal lobe and may decrease with age. In contrast, diminished motor activity, or hypomotor seizures, tends to arise from temporal or parietal locations.²⁴ In children younger than 7 years, frontal lobe epilepsy presents with subtle behavioral changes that differ from those in adolescents or adults. Frontal lobe seizures may also present with a diffuse warm feeling throughout the body or as an altered sensation in the body. Postictal wiping of the nose can occur in patients with frontal lobe seizures; however, this is more common in those with seizures of temporal lobe origin.³⁰

Benign rolandic epilepsy is one of the most common childhood epilepsies, with an estimated incidence of 5 to 15% of pediatric epilepsies.³¹ It is characterized by transient simple partial seizures with hemiparesis, facial palsies, difficulty swallowing, hypersalivation, and oromotor apraxia.³² These seizures have a typical presentation pattern in children 3 to 10 years of age and may spontaneously remit by adolescence. The seizures frequently occur during sleep or shortly after awakening, and neurocognitive studies are often normal in these children.³¹ Multidisciplinary epilepsy teams, however, are becoming increasingly aware of a certain population of children in whom rolandic seizures were previously diagnosed who present at earlier ages (younger than 6 years) and have progressive cognitive impairments. These children are diagnosed with malignant rolandic epilepsy³³ that is refractory to antiepileptic medications and whose semiology may change. The term *malignant* is used to identify the increased frequency and clustering of seizures, resistance to medical therapy, and longer duration of the disorder. The seizures may also involve somatosensory symptoms and can generalize to tonic-clonic seizures.^{32,34}

73.4.3 Parietal Lobe Seizures

Parietal lobe seizures account for only 5% of partial seizures despite their large cortical volume.³⁵ The semiology of the parietal lobe is difficult to detect because epileptic activity may rapidly spread from ictal foci to adjacent lobes, triggering events that are seen as originating from the temporal or occipital region.³⁶ The parietal lobe subserves several eloquent cortical functions, including integration of visual information, language, praxis, and attention. Parietal lobe damage results in apraxia, agnosia, agraphia, acalculia, left-right disorientation, hemineglect, and altered body image.³⁷

Parietal lobe seizures involve visual or somatosensory auras that can be localized to a particular region of the patient's body.³⁸ In addition, parietal lobe seizures present with ictal pain, complex visual hallucinations, and autoscopia (out-of-body experience).³⁶ Seizures originating from the parietal region can quickly spread to the temporal lobe and present with semiologies similar to those of temporal lobe epilepsy.

73.4.4 Occipital Lobe Seizures

Occipital lobe epilepsies account for an estimated 8 to 28% of partial epilepsies in children,³⁸⁻⁴⁰ and some of the earliest reports of seizure semiology in occipital lobe epilepsy were described in 1885.⁴¹ A large number of patients will have Panayiotopoulos syndrome, the second most common childhood epilepsy after benign childhood epilepsy, and do not require surgical intervention because there is a significant rate of spontaneous seizure remission in these patients.⁴² It is estimated that only 2% of epilepsy procedures are done in children with occipital lobe seizures.³⁹ The ILAE has divided occipital lobe epilepsies into two types depending upon early or late onset. Early-onset seizures occur at a median age of 5 years and present with non-visual symptoms, such as vomiting, eye deviation, and tonic head movements. Late-onset seizures occur at a mean age of 9 years and most commonly involve visual hallucinations, followed by illusions, palinopsia (persistence of an image or its recurrence), and visual auras, as well as ictal blindness and

amaurosis with loss of portions of the visual fields.^{40,43} If the seizures spread, temporal lobe automatisms or focal motor seizures may develop if the supplementary motor cortex is affected.³⁹ Children with occipital lobe seizures are also found to have lower verbal and performance IQs and can be at increased risk for neurobehavioral disorders.⁴²

73.5 Diagnostic Work-up

The diagnostic work-up required for children with ETLE has become more advanced throughout its evolution and now includes a host of technologies routinely used by epilepsy centers to identify the etiology of seizures and ictal onset.⁴⁴ The utilization of each test depends largely upon the suspected etiology, and tests may proceed to more advanced technology if the information is discordant. Adding a further layer of complexity to the analysis of children with ETLE is the changing nature of seizure types, as in infants who present with generalized or partial seizures that can evolve to complex partial seizures, absence, generalized tonic-clonic, or myoclonic seizures.

73.5.1 Noninvasive Electroencephalography and Video Electroencephalography

EEG serves as the foundation of inquiry into epilepsy in children. Video EEG units have the added power of coupling longitudinal electrophysiologic data with clinical manifestations to determine the effect of a seizure on a child's function.

Interictal epileptiform discharges (IEDs) often originate from an area of the cortex that is somehow associated or responsible for ictal discharges. In temporal lobe epilepsy, these discharges can be associated with mesial temporal sclerosis or temporal tumors. In ETLE, the use of EEG to identify focal IEDs, such as those seen with focal cortical dysplasia (FCD), is associated with improved surgical outcomes for seizure-free activity. Ictal EEG recordings are helpful for localization in cases with a high degree of recording concordance. Extra attention must be paid in cases of ETLE in which parietal and occipital lobe seizures can cause a false localization. ETLE in the frontal lobe can frequently present with focal rhythmic fast activity on EEG. Scalp EEG source localization is an additional technique used to identify the epileptic center of activity and may be of use in preoperative studies of ETLE.⁴⁵

Although EEG remains the cornerstone for the evaluation of ETLE, it has limitations when pediatric patients present with the synchronous onset of epileptiform activity over a diffuse epileptogenic area, which represents multilobar pathology. Additionally, there can be poor localization with EEG, an absence of IEDs, or no appreciable EEG changes with clinical seizure onset. These limitations reduce the likelihood of identifying the ictal onset in ETLE and warrant the performance of additional diagnostic studies. High-frequency oscillations (100 to 500 Hz) are associated with epileptic regions in the hippocampus and neocortex⁴⁶ and may be used as biomarkers for epileptogenic regions.⁴⁷ Prospective studies to correlate high-frequency oscillation rates with zones of seizure onset are ongoing and will determine the predictive value of this technology.^{48,49}

73.5.2 Neuroimaging

Neuroimaging modalities and their uses in diagnosing the etiologies of pediatric ETLE have seen significant changes over the past 20 years and may be the most important sources of improved presurgical planning in children with ETLE. With improved resolution, magnetic resonance (MR) imaging has helped to detect previously unidentified brain lesions. Field strengths in excess of 1.5 tesla (T) and phased-array coils are increasingly being used for volumetric studies and localization in a clinical setting.⁵⁰ The use of 3-T imaging increased the identification of lesions in 65% of patients previously reported to have negative images.^{51,52} Although lesions are more clearly viewed, their contribution to the onset or persistence of epileptiform activity must be correlated with clinical and electrophysiologic data, such as EEG recordings.

Seizure-free outcomes are improved when EEG and neuroimaging modalities are concordant.^{53,54} If, however, the patient has multiple lesions or other associated malformations of cortical development (MCDs), additional evaluation with diagnostic studies is warranted. Despite the increasing reliance on MR imaging to localize lesions, seizure freedom has been successfully achieved⁵⁵ in patients in whom no appreciable lesion could be identified on MR imaging.^{56,57} The use of intracranial EEG (iEEG),⁹ positron emission tomography (PET), and ictal single photon emission computed tomography (SPECT) improved surgical outcomes in 75% of patients, with a 37% seizure-free rate in cases in which MR imaging was unsuccessful in localizing a lesion. Surgery remains a treatment option even when the results of MR imaging are equivocal.

Questions arise about which pediatric patients should be screened with MR imaging. When a child presents with a first-time seizure, computed tomography (CT) is usually performed in the emergency department, with one-third of these patients later determined to have epilepsy. Previous studies have shown that 7 to 24% of CT procedures identify abnormalities warranting management.⁵⁸ MR imaging is the next imaging modality for evaluating children; however, 50% of imaging studies in patients with idiopathic generalized epilepsy are normal. The threshold to obtain MR imaging in infants is lower because they are at an increased risk for developmentally related malformations that may manifest without otherwise localizable features.⁵⁴ Children who should also undergo early MR imaging are those with focal seizures, abnormal or focal neurologic examinations, developmental delay or regression, generalized epilepsy, signs of increased intracranial pressure, or syndromic manifestations or family histories of epilepsy.⁵⁸ Pediatric neuro-radiologists familiar with developmental changes in the appearance of the cortex are required for the optimal screening of MR imaging findings.⁵²

Many protocols have been developed by various centers to optimally image pediatric epilepsy-related pathologies. Most surgical centers require thin-slice volumetric T1-weighted images with and without contrast, T2-weighted images, and FLAIR (fluid-attenuated inversion recovery) images in an axial, coronal, and sometimes sagittal reconstruction. Volumetric MR images have also been useful to identify hippocampal volumes to determine if a component of mesial temporal lobe sclerosis is present. MR imaging is paired with MR spectroscopy to identify markers of neuronal loss and the presence of certain tumors or

other abnormalities. MR imaging has helped not only to identify congenital MCDs, tumors, and other abnormalities, but also to confirm in an intraoperative setting the complete resection of lesions, thereby reducing the need for additional surgery.⁵⁹ Still, the lesions of 20 to 30% of patients are not localized with MR imaging.⁶⁰

As the number of cryptogenic cases of ETLE increases at pediatric epilepsy centers, newer MR technologies are pushing the boundaries to identify underlying lesions. These techniques are being applied primarily to FCDs that result from abnormal cortical development and migration defects. Structural MR imaging is employed to look for subtle abnormalities in gyral and sulcal morphometry. Voxel-based intensity and morphometric studies are used along with quantitative image analysis⁶¹ to identify lesions through automated pattern recognition.⁵⁷

Diffusion tensor imaging (DTI) and tractography rely on the anisotropic diffusion of free water to identify white matter tract organization. The use of DTI for preoperative planning⁶² is rapidly expanding, and DTI has aided in the identification of optic tract,⁶³ motor strip, and other eloquent cortical involvement in and around epileptogenic foci. DTI can also reveal changes that occur in patients with certain pathologies⁶⁴ or with language and memory impairments, and the results can be correlated with neurocognitive outcomes.⁶⁵ DTI is used to obtain high-resolution functional and structural data that can guide the stereotactic placement of subdural EEG electrodes in ETLE cases.⁶⁶ DTI improved surgical decision making in 66% of patients, and its use is correlated with improved surgical outcomes for ETLE.⁶⁷ Following surgery,⁶⁸ DTI may also be employed to assess the plasticity of the underlying cortex and remodeling in fiber bundles.⁶⁹

73.5.3 Functional Magnetic Resonance Imaging

Functional MR imaging (fMRI) is an additional use of MR imaging that maps cerebral activity by detecting changes in blood flow while a patient performs associated tasks. fMRI works by detecting the level of deoxygenated hemoglobin, which decreases when a cortical area is activated, thereby increasing blood flow to that cortex.⁷⁰ This technique, called blood oxygenation level-dependent (BOLD) contrast fMRI, has been useful in mapping language function.⁷¹ fMRI can be successfully performed in children as young as 5 years of age in whom the lateralization of motor and other functional capacities has already been established.^{27,58} fMRI techniques are used to lateralize language function in the temporal lobe to aid in preoperative evaluation.⁷² fMRI can also be used in preoperative studies to assess motor tasks.^{73,74}

73.5.4 Functional Connectivity Magnetic Resonance Imaging

Recent advances in fMRI use spontaneous BOLD fluctuations to map functional connectivity in the brain. A normal brain that is not performing a task exhibits slow (<0.1 Hz) fluctuations in the BOLD signals that correlate with neuronal activity⁷⁵ in a distinct functional network. Functional connectivity MR imaging (fcMRI) can be performed in children at rest to identify

sensorimotor and language cortical regions. There are several advantages to using fMRI in children because they are not required to perform an age-dependent or cognitive-dependent verbal or motor task. Thus, children may be investigated at earlier ages. In addition, a single study will allow the deciphering of various functional connectivity networks with improved signal-to-noise ratios.⁷⁶ The future use of fMRI in preoperative evaluations may improve our understanding of anatomical connectivity and function in pediatric ETLE.⁷⁷

73.5.5 Positron Emission Tomography

PET is increasingly being used to determine areas of ictal onset by identifying hypometabolic regions corresponding to abnormal cortex.⁷⁸ PET uses fluorodeoxyglucose (FDG) to approximate metabolic activity in the cortex. Hypometabolic FDG-PET has been used to identify and localize regions of suspected epileptogenesis that require additional investigation. In addition, α -methyl tryptophan (AMT)-PET is used to differentiate between epileptogenic and nonepileptogenic lesions in patients with tuberous sclerosis and MCDs. Finally, flumazenil (FMZ)-PET⁷⁹ can identify epileptic cortex beyond an abnormality on MR imaging by detecting areas with decreased binding to γ -aminobutyric acid A receptors.¹ PET has the advantage of using different receptor binding sites in the brain, which facilitates ongoing investigations into the neurobiology of epileptogenesis.⁷⁸

73.5.6 Single Photon Emission Computed Tomography

SPECT approximates perfusion to a suspected area of cortical involvement in epileptiform activity following the injection of a radioactive tracer. Focal increases in perfusion reflect epileptic activity. Ictal SPECT measurements approximate metabolic demands and may localize hypermetabolic lesions like FCD when conventional MR imaging is equivocal. Studies can be compared in which subtracted ictal–interictal SPECT data can increase the sensitivity for detecting differences between perfusion rates in the ictal and interictal states. The resulting information can be co-registered with MR imaging (subtraction of interictal from ictal SPECT co-registered to three-dimensional MR imaging, or SISCOM) to identify epileptic foci.⁸⁰ In cases of tuberous sclerosis⁸¹ and other multifocal abnormalities, SPECT is especially useful for defining the epileptogenic zone. Co-registration with MR imaging can also be employed to guide and implant subdural electrodes. Ictal SPECT has limitations, however, because it is difficult to synchronize the timing of the injection radioactive tracer with ictal onset, and close video EEG and clinical monitoring by a trained multidisciplinary epilepsy team are required.

73.5.7 Magnetoencephalography and Magnetic Source Imaging

MEG is a more recent technology that is increasingly used to identify magnetic fields and dipole clusters produced by cortex with interictal epileptiform activity. In turn, MEG can detect electrical activity that is parallel to the cortex and tangential to the convexity.⁸² The magnetic fields are not dissipated by the

intervening structures of the skull and scalp, which aids in localization. MEG results have been verified by correlation with iEEG recordings and have improved localization in equivocal cases in which video EEG and MR imaging appeared to be discordant. The accuracy of MEG for predicting surgical outcome was compared with that of MR imaging and various EEG techniques and was found to be second only to that of intracranial subdural EEG monitoring.^{83,84} In a study of ETLE, concordance between MEG and iEEG data in localizing epileptiform discharges corresponding to the ictal zone was found in 91% of children.⁸⁵ The future applications of MEG may reduce the number of patients requiring invasive studies, leading to a more cost-effective and safe use of diagnostic studies in children.⁸⁶

Failure to remove regions with active preoperative MEG dipoles predicts postoperative seizure recurrence.^{87,88} MEG is being increasingly used to reduce the number of studies required to evaluate infants undergoing hemispherectomy.⁸⁹ Some epilepsy centers are turning to MEG as a primary modality to identify the ictal area during preoperative planning and resection.⁹⁰ MEG has the ability to map sensorimotor, language, and other functional capacities, and its accuracy is comparable to the perceived gold standard of iEEG monitoring.⁹⁰

In magnetic source imaging (MSI), MEG and MR imaging data are combined to optimize the results of each modality for structural and functional data. Three-dimensional images can be generated to delineate the morphological and functional changes wrought by epileptogenic tissue.⁹¹ Epileptic foci can be accurately pinpointed with this technique and compared with eloquent cortical regions or detectable structural abnormalities.⁹² This information can guide surgical resections or lead to palliative procedures, such as multiple subpial transections. MSI correlates with surgical findings in more than 89% of cases⁹³ and has a reported accuracy of 100% in ETLE cases.⁹¹ MSI improved localization data in 35% of patients and altered treatment decisions in 10% of patients. In cases of tuberous sclerosis, MSI has a reported 100% sensitivity, 94% specificity, and 95% accuracy in identifying epileptogenic lesions in children.⁹⁴ MSI data can also be used to predict surgical outcomes.^{31,95}

73.5.8 Wada Test

The intracarotid injection of sodium amobarbital (Wada test) is used to study the function of a cerebral hemisphere. Following injection, the ipsilateral hemisphere is temporarily inactivated, and language and memory function in the contralateral hemisphere can be tested to localize these functions. Wada testing is limited because it is invasive, and it may be supplanted by fMRI or MEG in the future.

73.5.9 Neurocognitive Testing

There is growing recognition that seizure freedom is not the only measure of a successful outcome postoperatively. A number of neurocognitive tests have been developed to monitor preoperative deficits and postoperative outcomes, with the goal of improving the pediatric patient's quality of life following intervention. Each patient undergoing surgical evaluation requires a complete neurocognitive evaluation to identify cognitive function, language skills, intelligence, attention, memory,

executive function, personality, behavior, and motor and sensory limitations. Children with epilepsy have a higher rate of comorbidities when compared with control groups. Childhood comorbidities in epilepsy include attention-deficit/hyperactivity disorder (ADHD), autism, depression, anxiety, developmental delay, and cognitive and behavioral abnormalities. Symptoms of ADHD were identified in 38% of children with epilepsy, and depression and anxiety were seen in 26% and 16% of epileptic children, respectively.⁹⁶ Epilepsy is found in 28% of autistic children.¹³ Finally, the incidence of mental retardation and cerebral palsy is upward of 38% in children with epilepsy.⁹⁷

Despite extensive evaluation and a combination of various noninvasive modalities to localize the epileptogenic region, a considerable fraction of children with medically refractory ETLE will require iEEG monitoring with invasive techniques. These patients often have normal or nonlocalizing imaging, widespread EEG abnormalities, or multiple lesions. To pursue subdural monitoring with grids, strip, and depth electrodes, input from an experienced epilepsy team is warranted.

73.6 Surgical Decision Making: Epilepsy Center Structure

Seizure freedom is the ultimate goal in a neurosurgical intervention for pediatric epilepsy. In some cases this may be an unachievable goal, however, and palliative procedures are offered to reduce the seizure burden. Managing the expectations of families adds a further layer of complexity to the treatment of ETLE.⁹⁸ As the scientific and clinical communities have increasingly recognized the difficulties associated with ETLE treatment, there is a preferred exclusion of patients based on extratemporal locations.⁹⁹ To obviate such an approach, patient selection and knowledge of the various syndromes and seizure types become essential components of surgical planning and decision making.¹⁰⁰ Parental angst may be offset by the collective experience offered by pediatric epilepsy centers for difficult cases.

Multidisciplinary meetings with epileptologists, neurosurgeons, radiologists, EEG technicians, neuropsychologists, pediatricians, therapists, and other associated healthcare providers facilitate the summation of the information collected for each child who is a potential surgical candidate. During these meetings, the diagnostic information obtained with video EEG, semiology, and neuroimaging, together with potential surgical planning, is used to frame possible solutions to reduce or eliminate seizure burden. As a result of collective experience and discussions, aided by improved diagnostic techniques, increasing numbers of children are being considered for surgical intervention. Cost analysis in developing countries reveals that lesions can be cost-effectively treated with limited resources. Ideal patients are those with lesions identified by MR imaging that have been co-localized with interictal and ictal EEG.⁹⁹

With a multidisciplinary approach and the success of surgery in ETLE, there is a growing trend to identify children as early as possible for surgical intervention and to select patients who are at high risk for failing medical therapies. The early identification of surgical candidates is one goal of surgical centers, where children can be evaluated expeditiously instead of waiting for prolonged unsuccessful medical treatments. There is a balance that must be struck in the early identification of children with

surgically amenable pathologies. Adequate medical therapy should be advocated while the selection of surgical candidates is improved. Children with infantile spasms, multiple seizure types, or recurrent seizures within 1 year of treatment are likely to progress to intractable epilepsy that may also require surgical intervention and are less likely to respond to medical therapies.²⁷ Patients who have syndromes associated with ETLE may also benefit, with surgery considered for those with Sturge-Weber syndrome, tuberous sclerosis, FCD, hemimegalencephaly, Rasmussen syndrome, or low-grade tumors. With a greater understanding of seizure types and the neurodevelopmental burden of seizures, it is clear that more children can now be helped.^{8,101}

There are also patient variables that make seizure-free outcomes less likely in surgical candidates. Diffuse lesions on MR imaging, seizures with a neonatal onset, a longer duration of epilepsy, psychiatric comorbidities, and IQs below 70 have all been associated with poorer postoperative outcomes. Patients undergoing multilobar resections are also less likely to achieve seizure-free status. In addition, the histopathologic diagnosis of a tumor is associated with an improved surgical outcome in comparison with FCD.¹⁰² The seizure-free outcomes of FCD type II may be better than those of type I as a result of improved visualization with MR imaging to aid complete surgical resection.

Epilepsy teams are also charged with evaluating the pediatric patients in follow-up, looking not only for degree of seizure remission or freedom but also for neurocognitive outcomes and, ultimately, the ability to function independently in society.

73.7 Surgery

The surgical resection of epileptic foci in pediatric patients began with Victor Horsley in 1886.⁸ Initial results from these efforts suggested a reduction in seizure frequency and tolerable clinical outcomes. With the later availability of EEG, Wilder Penfield pursued epilepsy surgery at the Neurological Institute in New York and later founded the Montreal Neurological Institute while pioneering the use of electrocorticography (ECoG) to guide surgical resections of epileptogenic tissue.¹⁰³ During his studies, Penfield focused primarily on adult pathology and temporal lobe epilepsy, but he also performed a significant number of surgeries for ETLE.^{104–109} This and other groundbreaking work slowly led to the expansion of surgical techniques in children.^{110,111} Continued progress in clinical studies in the 1980s and 1990s led to the increasing appreciation that younger patients with ETLE were surgical candidates. While hemispherectomy and other disconnection surgeries were gradually adopted into the realm of pediatric epilepsy, a host of new surgical techniques, paired with advancements in diagnostic techniques, paved the way for extratemporal surgery in a pediatric population.

73.7.1 Single-Stage Procedures

The most straightforward application of surgery for the treatment of ETLE in children is single-stage surgery for lesionectomy or lobectomy. When the aforementioned diagnostic tools (MR imaging, EEG and clinical data) are concordant in their localization of a lesion responsible for seizures,

surgical resection is pursued. Children with a resectable offending lesion have the best seizure-free outcomes, with results related to a gross total resection. Advanced diagnostic tools like PET and SPECT may be avoided in children in whom concordant results identify a single lesion.

During surgery, ECoG is often used to identify interictal data and functional cortical regions. ECoG remains the gold standard for the evaluation of an ictal onset and can be performed during surgical resection, after the implantation of subdural grids, or following surgical resection to evaluate areas for ongoing epileptiform activity. General anesthesia without benzodiazepines is preferable.¹¹² A larger craniotomy will allow mapping of the cortical surface. Depth electrodes may be placed with frame-based or frameless stereotactic systems that can also be used to guide surgical resection. ECoG requires that grounding and reference electrodes be placed subgaleally or on the scalp surface.

Cortical mapping is possible during surgery with somatosensory evoked potentials (SSEPs) and bipolar cortical stimulation.¹¹³ Low stimulus settings can be used to avoid eliciting seizures and may be tailored according to the age of the patient. Settings for cortical stimulation may include 3- to 5-mA, 50-Hz biphasic square wave pulses with a duration of 0.3 millisecond.¹¹⁴ The current can be increased in small intervals until an ictal event or afterdischarge is seen or if a current of 15 to 16 mA is reached. Likewise, the pulse duration may be increased in a stepwise manner until a duration of 1 millisecond is achieved. The central sulcus may be identified by phase reversal in SSEPs, and motor evoked potentials may be used to further identify regions of the motor cortex. The response to motor cortex stimulation is related to the age of the patient, with infants showing no response given the underdeveloped myelination of the major motor pathways. Seizures that are elicited on ECoG can be aborted with the application of cold saline to the cortical surface.^{115,116}

After ECoG and cortical mapping, resection of the lesion is pursued while the boundaries of eloquent cortex are respected. Multiple subpial transections, discussed later in this chapter, may be used if the ictal region involves eloquent cortex. Efforts should be made to avoid the retraction of normal brain to avoid vascular compromise, infarct, and postoperative edema. If a lesion is present, ultrasound or frameless MR imaging neuronavigation may aid in identifying the limits of surgical resection, and a lesionectomy can be performed. If only epileptogenic cortex is present, a corticectomy is performed, in which the gray matter is removed with a subpial dissection technique down to the white matter. Care is taken to follow the gyral folds to the depths of the sulcus to avoid leaving epileptic tissue behind. ECoG after resection allows confirmation of complete resection of the ictal focus. Postoperatively, anticonvulsants are continued according to the patient's previous home regimen and may be tapered based on close observation by pediatric neurologists.

73.7.2 Two-Stage Procedures

The current technology of diagnostic imaging and electrophysiology can be stretched to its limits as the complexity of cases addressed by pediatric epilepsy teams (younger ages of patients, increased comorbidities, syndromic findings) increases. Frequently, discordant data cloud localization of the area of ictal onset. One technique that improves a neurosurgeon's ability to

diagnose and treat ETLE is the use of subdural electrodes for neurophysiologic recordings and ECoG.¹¹⁷

The implantation of electrodes for iEEG monitoring has gained popularity in the last decade, largely to address the number of patients who have discordant diagnostic studies or who have lesions adjacent to eloquent cortex.^{32,118} The benefit of iEEG is that children who were previously not surgical candidates can now undergo invasive studies so that a surgical approach can be tailored to their particular underlying pathology. iEEG with electrodes allows longitudinal monitoring, which can better identify epileptogenic cortex and further map eloquent areas. Ictal and interictal activity can be studied, and cortical stimulation can be employed to identify motor, speech, and language areas in children who are of an age to have these localizable functions identified. In addition, stereotactically placed depth electrodes are used to probe subcortical regions where activity is not otherwise recorded by superficial grid arrays.^{119, 120} Neuronavigation with frame or frameless stereotactic systems is also routinely employed to take advantage of MR imaging that has been fused with MEG, PET, and/or SPECT data. The combination of neuronavigation with these diagnostic modalities improves surgical planning and identifies nearby eloquent cortex that limits resection.

The first stage of surgery involves using the aforementioned diagnostic studies to identify areas of interest either in one or both hemispheres that are candidates for iEEG monitoring. Preoperatively, epileptologists and neurosurgeons can design an optimal array of strip, grid, and depth electrodes to obtain the necessary electrophysiologic information and to maximize coverage of the cortical surface (► Fig. 73.1a). Detailed thin-cut MR imaging with venography or arteriography can aid in surgical planning, especially if stereotactic localization is used. Subdural grids are especially useful for assessing the interhemispheric cortex, orbital frontal cortex, mesial temporal lobe, and cingulate gyrus. The implanted arrays are silicon-covered platinum-indium electrodes that are MR compatible and allow postoperative imaging to confirm anatomical localization (► Fig. 73.1b,c). After placement of the subdural electrodes, epilepsy teams will note the location and orientation of the arrays, often with intraoperative photographs for later matching to imaging and iEEG data (► Fig. 73.1d). To augment the information offered by surface array coverage, depth electrodes can safely be employed in cases of ETLE to target cortex that may lie tangentially to conventional strip or grid electrodes (► Fig. 73.2a). The electrophysiology of sulci and regions like the interhemispheric cortex and frontal and temporal opercular cortex may also be probed (► Fig. 73.2b) with depth electrodes.¹²¹

Electrode wires are tunneled out through the skin with separate stab incisions (► Fig. 73.2c) and anchored to the dura and skin with purse-string sutures. This reduces the opportunity for electrode migration during closure of the surgical incision and postoperative studies. A duraplasty may be necessary to accommodate the bulk of the arrays. Replacement of the cranial bone flap (► Fig. 73.3a,b) depends upon surgical technique because there are options to hinge the bone flap without complete removal during surgical exposure. Other options are to replace a fully removed bone flap after lead placement or to store it in a freezer for later replacement. Each technique has its advantages and disadvantages. A hinged bone flap obviates the need for additional titanium hardware placement and preserves

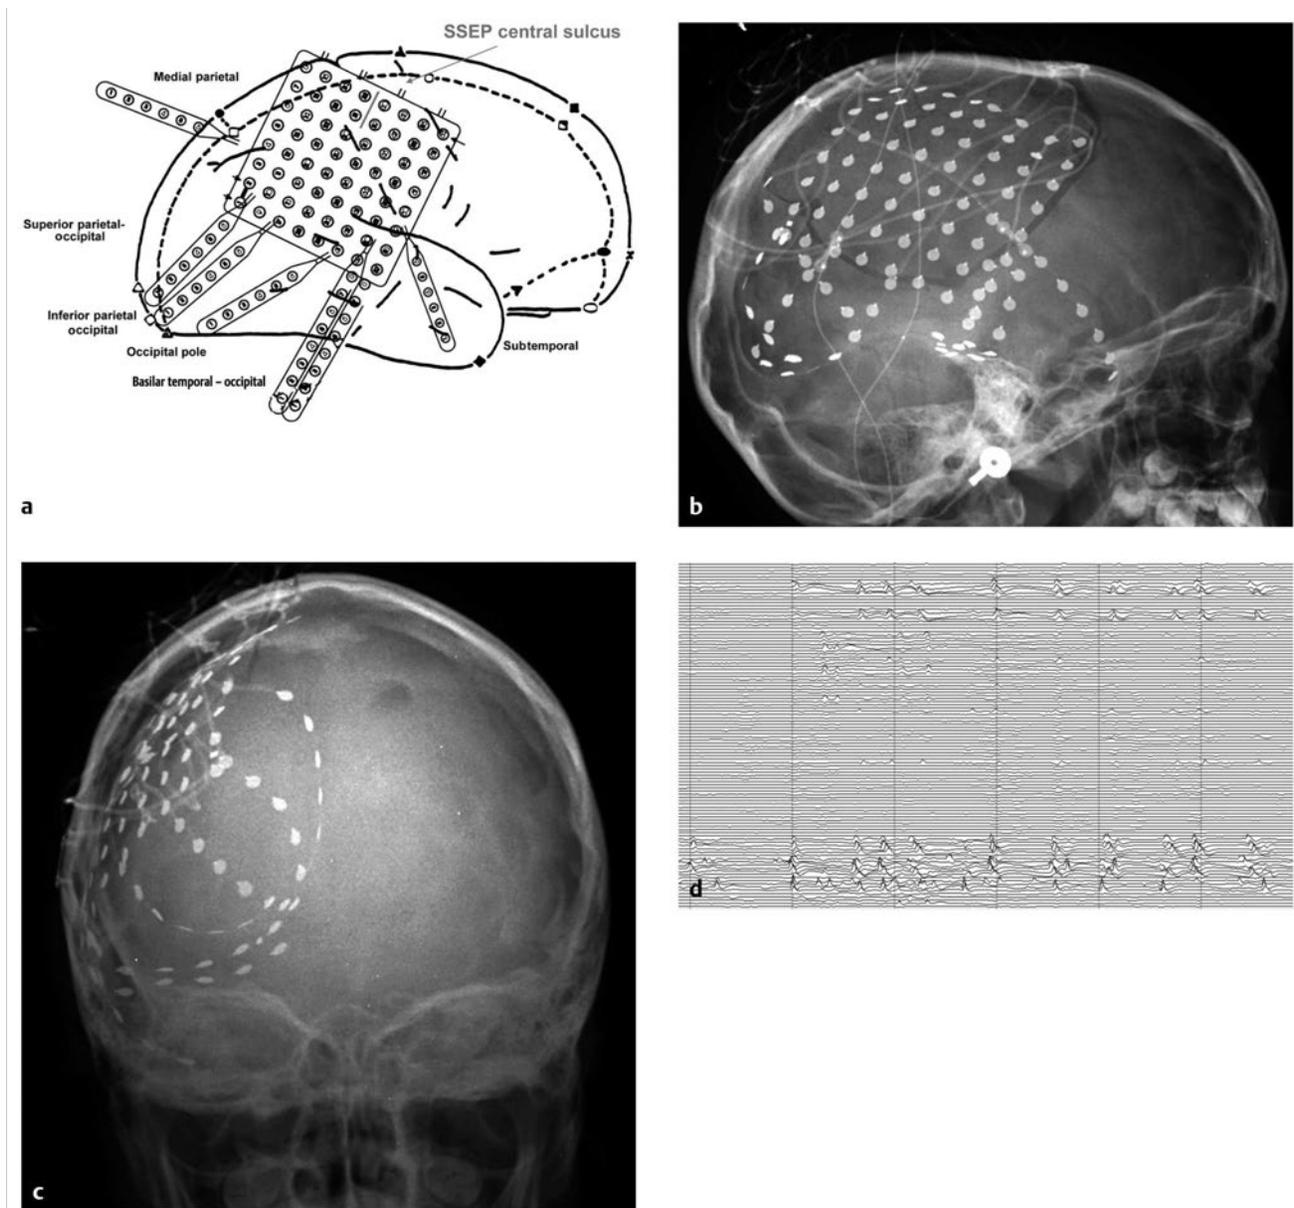

Fig. 73.1 Ictal localization for a parieto-occipital resection. (a) Pictorial representation for planning the placement of the grid array with respect to the cortical surface. The 8 × 8 grid can be seen, with adjacent six-lead strip electrodes overlying various portions of the cortex. The central sulcus is marked under the overlying grid. SSEP, somatosensory evoked potential. (b) Postoperative lateral plain radiograph revealing placement of the array of grid and strip electrodes for ictal localization. The underlying craniotomy can be seen with lucency in the calvaria. (c) Postoperative anteroposterior plain radiograph revealing the same placement of the grid array and strip electrodes. (d) Electroencephalogram from placement of the grid and electrodes localizing epileptic activity with spike-wave complexes to the occipital lobe.

anatomical perfusion and aesthetics. There may, however, be limitations in the degree of exposure. Replacement of a bone flap following lead placement protects the underlying cortex and monitoring devices, but it may constrict the additional volume of subdural grids, subdural fluid, and edema, potentially causing a mass effect. Finally, storing the cranial flap in a freezer may alter the native osteogenic repair following replacement in the second stage, resulting in bone flap resorption.

Temporalis fascia and skin are approximated, and postoperative radiographs in the anterior–posterior and lateral positions reveal the anatomical orientation of the grid (► Fig. 73.3b).

Sterile dressings are applied, and prophylactic antibiotics are continued through the second-stage resection and electrode removal. Video EEG can then be performed while the child’s medication is tapered as necessary to elicit habitual seizures. Correlation of the electrophysiologic data with clinical seizure onset is followed by cortical mapping to identify eloquent cortex. The purpose of obtaining iEEG data is to use analysis of the IEDs to localize the ictal onset and epileptogenic tissue that requires excision.¹²² Adequate ictal data are required to proceed to a surgical resection. The presence of focal high-frequency oscillations (>20 Hz) identifies more than 85% of patients with

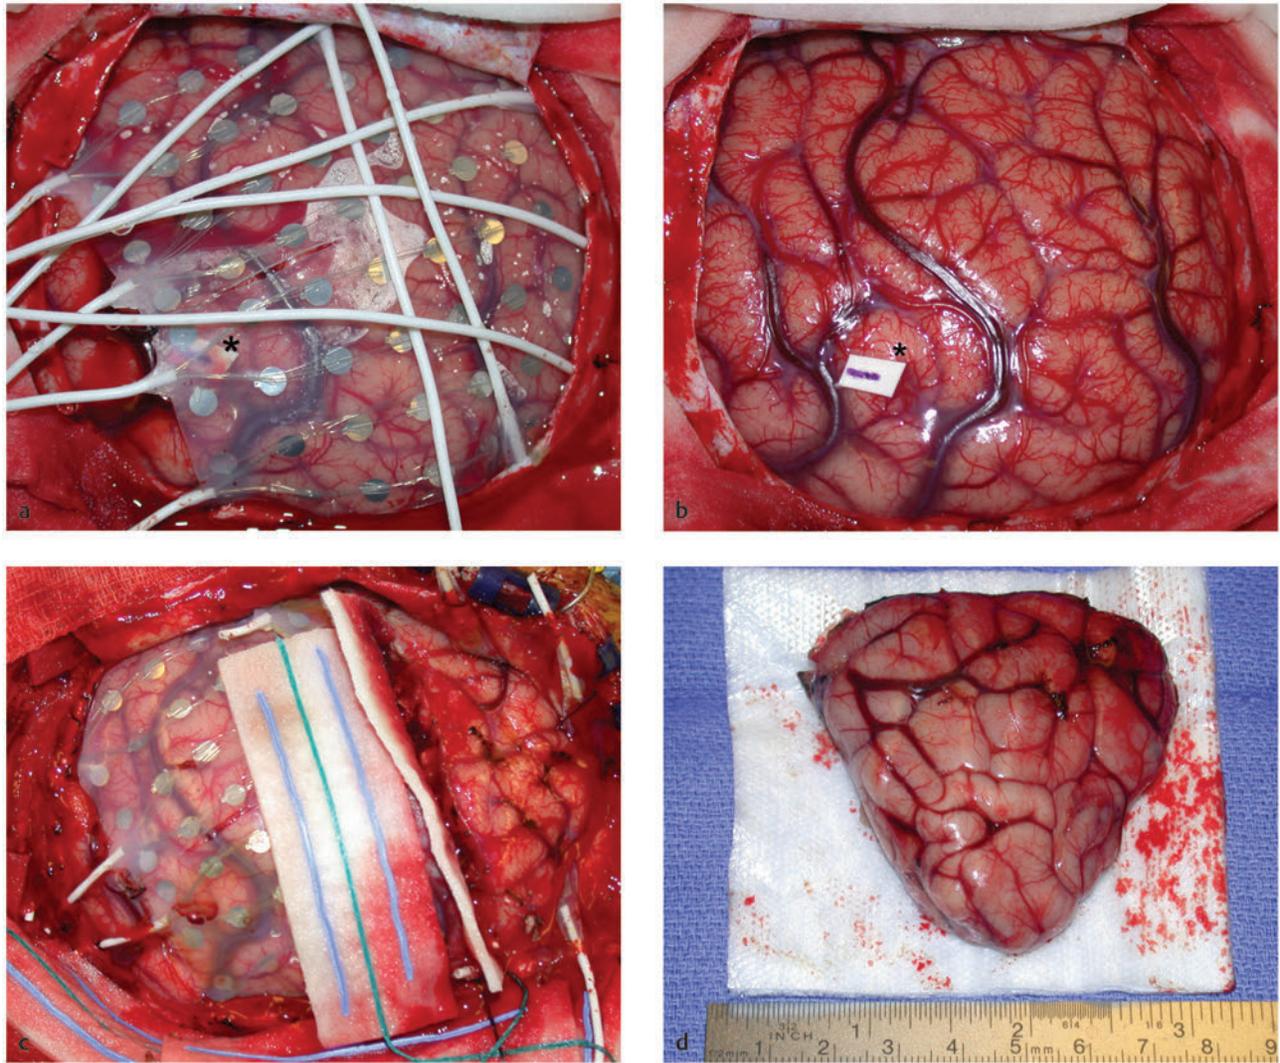

Fig. 73.2 Intraoperative photographs from an occipital lobe resection. (a) This photograph reveals the grid array over the affected cortical surface. Asterisk (*) represents underlying hand motor cortex. (b) Image of the cortex with the grid array removed and revealing the underlying mapped hand motor cortex. Asterisk (*) represents the hand motor cortex adjacent to the placed marker. (c) Intraoperative photograph revealing the initial resection bed. The grid is left in place to guide resection of the ictal focus. The beginning of a corticectomy is seen. (d) Photograph of the en bloc resected epileptogenic tissue.

ETLE who are likely to achieve a seizure-free outcome⁶⁰ and may play a role in localization of the seizure onset. Studies are ongoing. Additional spectral analysis for the presence of high-frequency oscillations on iEEG data in pediatric cases of ETLE may yield additional insight as to who may benefit from surgical resection.⁴⁵

Before the second stage, MR imaging is often performed to identify the cortical orientation of the arrays, and it allows the gyral anatomy to be understood in relation to the iEEG data. Radiographs before surgery are used to verify if the leads have migrated from their position on immediate postoperative studies. Changes in surgical planning may be warranted if shifting of the electrodes is suspected. The second craniotomy is performed, and the area for planned resection is marked before the arrays are moved (► Fig. 73.3c,d). A resection of the cortex is completed, and intraoperative ECoG is used to ensure that the in-

volved epileptogenic areas have been successfully removed. Intraoperative ECoG may show decreased spike frequency as a result of general anesthesia.³⁴ During surgery, epileptogenic tissue may be identified involving eloquent cortical functions, or there may be large cortical draining veins whose sacrifice could lead to edema and additional seizures¹¹⁸ (► Fig. 73.3e,f). Multiple subpial transections, a technique described later, are employed in areas of residual epileptic discharges in eloquent cortex.

There are disadvantages to the placement of subdural grids in pediatric patients. These include additional surgical exposure; the risk for perioperative complications of anesthesia, blood loss, and infection; subdural fluid collections; cerebrospinal fluid leak; strip electrode malfunction necessitating surgical replacement; pneumocephalus; and mass effect.¹²³ Monitoring in pediatric patients may also be less well tolerated for prolonged periods of time.⁸ Although concerns exist regarding prolonged

A small strip of hair has been removed and the skin prepared for incision. The head is placed parallel to the floor. (b) Postoperative lateral plain radiograph revealing parietal placement of the grid and strip electrodes for ictal localization. The underlying craniotomy can be seen. (c) This photograph reveals the grid array over the affected cortical surface. The asterisk (*) represents the underlying hand motor cortex. (d) Image of the cortex with the grid array removed revealing the underlying mapped hand motor cortex. Asterisk (*) represents the hand motor cortex adjacent to the placed marker. Note the large cortical draining veins. (e) This photograph shows the grid array left in place and cut to reveal the underlying epileptogenic cortex. The wires have also been trimmed to facilitate exposure. (f) Resection bed following removal of the epileptogenic tissue. The large cortical draining vein has been preserved and hemostasis maintained.

iEEG monitoring in children, reports indicate that the rate of culture-positive infections is approximately 6%,¹²⁴ which is comparable with that for other cranial procedures.

The clinical care of patients who are candidates for iEEG requires special consideration. The use of valproate, which may limit platelet function and increase the risk for perioperative intracranial hemorrhage, must be limited and the patient switched to a new AED. Awake craniotomies in children are also limited because in most cases children are noncompliant¹²⁵ and cannot effectively communicate.¹²⁶ Neuroanesthesia may include the use of dexmedetomidine,¹²⁷ an α -agonist that can be titrated for awake-asleep periods to facilitate cortical mapping.³⁰ Of the children who undergo prolonged iEEG monitoring, 14% will not subsequently receive surgical resection. Children with preoperative normal neurologic examinations, multifocal regions of ictal onset, or involvement of a critical eloquent area may not undergo surgical resection.¹²⁸

A three-stage procedure has been described in which after the second resection, new subdural electrodes are left in place for a second period of extraoperative monitoring. Multistage epilepsy surgery may offer the benefit of identifying areas of incomplete resection, especially in cases of multifocal disease. This technique may decrease the need to take the patient back for an unplanned resection of epileptogenic tissue that is later discovered.¹²⁹ The elevated risk for infection and perioperative risks must be considered before this strategy is employed.

73.7.3 Disconnection Procedures

Posterior disconnections have also been described when epileptogenic tissue is identified in the temporoparieto-occipital regions. An anterior temporal lobectomy can be combined with disconnection of the parieto-occipital lobes by preserving the vein of Labbé and the sylvian vessels. The incision is started on the superior temporal gyrus (T1) and carried to the trigone.¹³⁰ The resection is then carried posteriorly to the postcentral gyrus and all the way to the vertex to reach the falx, while all white matter is transected. Forniceal connections are then sacrificed just anterior to the splenium to interrupt hippocampal output.¹³¹

73.7.4 Palliative Epilepsy Surgery

Although the primary goal of surgical intervention in ETLE is to obtain a seizure-free outcome, there are other meaningful outcomes that must be considered, such as reducing the seizure burden and the comorbidities associated with frequent seizure activity. Palliative epilepsy surgery has been developed, with several techniques focusing on just such outcomes when freedom from seizures is deemed unobtainable. The benefits of pursuing palliative surgical approaches are that AEDs can be titrated or changed to reduce the cumulative side-effect profile and that certain types of seizures, such as atonic drop attacks, that may be impairing a child's daily quality of life, can be eliminated.

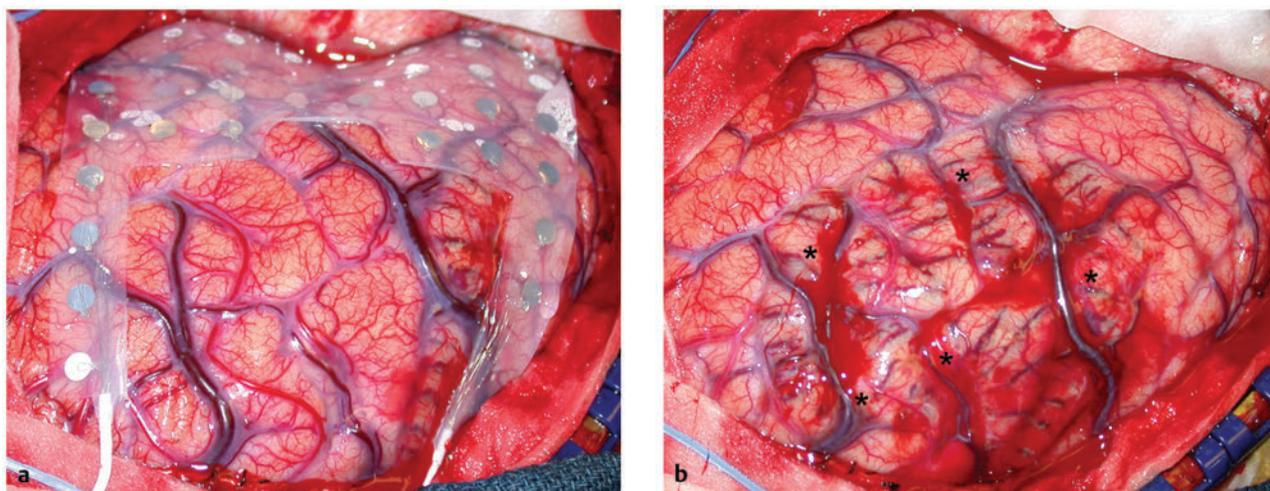

Fig. 73.4 Multiple subpial transections (MSTs) of affected cortex. (a) Intraoperative photograph revealing the affected cortex as determined by intraoperative electrocorticography. A portion of the grid array has been left in place to guide the MSTs. (b) Photograph of the same cortical region following the MSTs. The asterisks (*) mark the areas where MSTs were performed in eloquent cortical regions.

Multiple Subpial Transections

Lesions in primary visual, motor, or language cortex may prevent or limit surgical resection, thereby reducing the likelihood of seizure-free outcomes. When diagnostic approaches have identified epileptogenic lesions in eloquent cortex, MSTs can be utilized to disrupt the horizontal spread of epileptogenic activity between the vertically arranged functional units of cortex.¹³² If the horizontal fibers are disrupted with transverse incisions, seizure frequency can be reduced while normal neurologic function is preserved. Meta-analysis reveals that MSTs alone¹³³ may achieve seizure-free rates approaching 60 to 70%, depending upon the seizure subtype.¹³⁴ MSTs can be performed alone or in conjunction with lesionectomy, but their use may be correlated with poor control of seizure frequency.¹³⁵ In an international survey,⁴ MSTs were the most infrequently used technique in children with epilepsy (in 0.6% of pediatric epilepsy cases).

The location for MSTs is determined with intraoperative ECoG to identify areas of persistent epileptiform activity following surgical resection of adjacent cortex (► Fig. 73.4a). The application of bipolar electrocautery at 5-mm intervals along an involved gyrus is followed by a sharp incision in the pia mater. The instrument used is commonly a wire “knife” whose end is bent to a right angle with a length of 4 mm in order to span the gray matter.¹¹³ Sharp transection with the MST knife is carried out perpendicular to the gyrus and to a depth of 5 to 10 mm by drawing the tool back along the subpial surface. Cortical vessels are avoided during this procedure (► Fig. 73.4b). Ongoing ECoG confirms the absence of spike-wave activity and a reduction in epileptiform activity.¹³³

Complications arising from MSTs are reported in 19% of patients in whom the technique was used alone and in 23% of patients in whom it was combined with lesionectomy.¹³⁴ Deficits include transient hemiparesis, dysphagia, and other neurologic deficits related to the underlying cortical function. Eloquent cortical function is maintained as long as there is minimal damage to the neocortical columns and their vascular supply.^{32,136}

Recurrence rates for seizures following MSTs are elevated, at 18% in long-term follow-up studies.¹³⁷

Cortical Cooling

Finally, experimental models have led to the development of cortical cooling with Peltier devices, a technology similar to that used in polymerase chain reaction (PCR) machines. In experimental settings, animals have shown decreased seizure frequency and abortion of seizures when exposed to cortical cooling.¹³⁸ With histopathologic evidence that the underlying cortex has not been damaged, there is hope that this technology can be incorporated into clinical use for children with ETLE.¹³⁹

73.8 Common Pediatric Pathologies

ETLE can arise from a number of different pathologies in the pediatric population, most of which are associated with abnormalities in the progression of cortical maturation. Any disturbance in this well-orchestrated process can lead to the formation of epileptic foci throughout the pediatric brain. Pathologies encountered in pediatric epilepsy will vary greatly depending upon the age of the patient. Ninety percent of the surgical cases in infants will be hemispherectomies or multilobar resections as a consequence of their having multifocal cortical dysplasia, hemimegalencephaly, or Sturge-Weber syndrome.²⁷ In contrast, 65% of patients older than 10 years will undergo focal resections as a consequence of having tumors or FCD.

Based on the classification of MCDs, four major groups of diseases can be identified as potential causes of ETLE in children.⁶ Disorders in the first group result from abnormalities in neuronal and glial cell proliferation and include microcephalic states, lissencephalies, macrocephalic states like megalencephaly, cortical dysplasias with and without abnormal cells, and neoplastic lesions, such as gangliogliomas and gangliocytomas. Disorders in the next group result from abnormal neuronal migration and

include subcortical band and other heterotopias. Diseases giving rise to MCDs in the third group result from the dysregulation of corticogenesis and cortical organization and include polymicrogyria and schizencephalies. Finally, diseases in the fourth proposed group result from malformations of unspecified origin, including inborn errors of metabolism secondary to mitochondrial and peroxisomal disorders.

Additional etiologies of pediatric ETLE include neurocutaneous disorders, vascular and perinatal insults and infections leading to meningoencephalitis, trauma, and various other syndromes (see box “Common Etiologies of Pediatric ETLE in Children with Surgically Amenable Disease (p.962)”). Identifying the etiology of ETLE is essential because counseling can offer families insight into the risks for disease in additional offspring and can aid in identifying the potential clinical course associated with the particular pathology. As the study of human molecular genetics substantially improves our understanding of the genetic underpinnings of the various ETLEs, specific medications and therapies may be attempted to address the underlying genetic impairment resulting in epilepsy.

Common Etiologies of Pediatric Extratemporal Lobe Epilepsy

- Glial and neuronal proliferation or apoptosis disorders
 - Microcephalies
 - Macrocephalies
 - Hamartomas (tuberous sclerosis, hypothalamic hamartoma)
 - Hemimegalencephaly
 - Dysembryoplastic neuroepithelial tumor
 - Ganglioglioma
 - Gangliocytoma
- Neuronal migration disorders
 - Subcortical band heterotopia
 - Heterotopia
- Cortical disorganization disorders
 - Polymicrogyria
 - Schizencephaly
- Malformations not otherwise classified
 - Mitochondrial metabolic disorders
 - Peroxisomal disorders
- Other
 - Stroke
 - Trauma
 - Infection
- Various syndromes
 - Neurocutaneous (Sturge-Weber, neurofibromatosis)
 - Lennox-Gastaut
 - Rasmussen
 - West
 - Ohtahara
 - Hemiconvulsion–hemiplegia–epilepsy
 - Landau-Kleffner
 - Dravet
 - Panayiotopoulos

Note: Representative examples of each group are given, indicating the breadth of pathology seen in children with surgically amenable disease.

73.8.1 Focal Cortical Dysplasia

Since its first description in 1971, FCD has come to be recognized as the most common cause of intractable seizures in children, accounting for approximately 50% of cases in a surgical series.⁴ FCD is an area of malformed cortex that is frequently associated with epileptiform activity in children and has been classified into a three-tier system based on histopathology.¹⁴⁰ FCD type I is abnormal cortical lamination with abnormal radial and/or tangential layering effects. To identify FCD type I lesions, multiple neuroimaging modalities are necessary and range from volumetric or voxel-based analysis to FDG-PET. Despite advances in diagnostic imaging, cases of isolated FCD type I can be difficult to identify and are associated with worse seizure-free control.

Type II is subdivided according to the presence of cytologic abnormalities in addition to disrupted cortical lamination. Dysmorphic and enlarged neurons without balloon cells are found in type IIa, whereas type IIb has the hallmark eosinophilic balloon cells with large cell bodies. Patients who have type II FCD are usually younger at seizure onset and have an increased seizure burden in comparison with patients who have type I FCD. Preoperative studies of FCD with MR imaging may identify several areas of focal cortical malformation. FCD type IIb often presents with dyslamination, blurring of the gray matter–white matter junction, and thickened cortex that is identified on T2-weighted and FLAIR images. Type IIb presents with the “transmantle sign,” a radiographic feature in which white matter changes taper from the gyrus toward the ventricle along a sulcus. FCD type IIa, however, can be more difficult to identify on MR imaging. In addition, type IIb has a unique electrophysiologic signature on stereotactically placed depth electrodes for iEEG recordings. There is an absence of background activity, with high-amplitude fast spikes followed by high-amplitude slow waves. Finally, a recent classification has established type III FCD, which is associated with hippocampal sclerosis (type IIIa), with adjacent glial tumor (type IIIb), or with an associated injury acquired early in life (type IIIc). Resection of the focal pathology in FCD is the best predictor of postoperative seizure freedom.¹⁴¹ Both MR imaging and EEG findings improve complete resection and the opportunity for seizure-free outcome.

73.9 Outcomes

To standardize outcome reporting, Engel et al defined a classification system for the postoperative evaluation of patients.¹⁴² The scoring system is based on four main classes. Patients in class I have complete freedom from disabling seizures or only simple partial seizures remaining. Patients in class II have rare disabling seizures with more than 90% seizure freedom. Class III outcomes are seen as worthwhile improvement, with seizure reduction of more than 50%. Finally, patients in class IV have appreciable change in seizure frequency.

When compared with those who underwent resection for temporal lobe epilepsy, pediatric patients who had ETLE resections were reported by numerous groups to have significantly worse Engel outcomes.¹⁴³ Seventy-five percent of children with temporal lobe epilepsy were reported to have Engel class I or II outcomes, whereas only 50% of those with ETLE had class I or II

outcomes.⁵³ The inability of extensive diagnostic studies with invasive or noninvasive techniques to identify an underlying lesion or epileptogenic zone likely contributes to the decreased rates of seizure freedom in children with ETLE. As more modern series¹⁴⁴ of ETLE surgery have been reported,¹³⁵ the benefits of advances in neurophysiology are appreciated.¹⁴⁵ In a report in which iEEG monitoring was used, 60% of children with frontal lobe epilepsy were seizure-free following resections of tumors, FCD, or gliosis.¹⁴⁶ Seizure localization with scalp EEG can be challenging, with rapid propagation, and iEEG has helped to improve surgical outcomes.

Postoperative EEG studies may also help to predict outcomes following surgery; an acute seizure in the first postoperative week is associated with worse seizure-free outcomes.¹⁴⁷ Acute postoperative seizures occur in approximately 26% of patients with ETLE and should trigger additional diagnostic studies to identify the etiology of the residual epileptic activity. Seizures during this period may result from the surgical manipulation of tissue, infection, hemorrhage, metabolic derangements, altered anticonvulsant medication levels, and residual epileptogenic tissue. The presence of postoperative IEDs has a positive predictive value of 52% and a negative predictive value of 71% for lower seizure-free rates.¹⁴⁸ However, postoperative EEG studies should be used with caution in attempts to predict surgical outcome because inconsistent results can be caused by the heterogeneity of the seizure etiology, duration of follow-up, and patient population being investigated.

Recent meta-analytical data have indicated factors related to seizure outcome in pediatric ETLE in comparison with temporal lobe epilepsy.¹⁴⁹ There was a significant association between Engel outcome and seizure semiology, with better results seen in patients who had complex partial seizures. Many authors have reported series in which preoperative imaging identified a lesion¹⁵⁰ and removal of the lesion was associated with a higher rate of success than could be achieved with a diffuse process or nonlocalizable lesion.¹⁴¹ Meta-analytical data¹⁵⁰ also confirm that a recognizable lesion on MR imaging is significantly associated with a better Engel I outcome.⁵⁷ Improved outcomes in cases with identified lesions are attributed to a possible shorter duration of epilepsy than in cases in which lesions were not localized, so that additional diagnostic investigations were required. MEG concordance with preoperative EEG localization of epileptogenic zones predicts better seizure-free outcomes.⁹⁵

Also impacting outcomes is the etiology of the seizures. For example, tumors at extratemporal locations are associated with a higher percentage of Engel class I and class II outcomes. FCDs have a better prognosis than nonfocal lesions.¹⁴⁹ Certain etiologies, such as meningoencephalitis and perinatal insults, may result in multifocal epilepsy, making it more challenging to obtain seizure freedom in these cases. Complete resection of ictal zones defined on MR imaging or EEG is significantly correlated with improved seizure-free rates.¹⁴¹ Confirmation of a lesion on pathology is also predictive of an Engel I outcome.¹⁵⁰

Neurocognitive studies looking at cases of ETLE and neurocognitive outcomes report that duration of epilepsy, age at seizure onset, and etiology are independently associated with lower IQs in children. Surgery for the various etiologies did not impact cognitive outcome.¹⁵¹ A child's outcome after these and other surgical procedures can be measured in terms of a

development quotient (DQ). The DQ takes into account the child's developmental performance in areas of cognition, intellect,¹⁵² and motor and other skills at his or her developmental age (DA). The DA can then be divided by the chronological age to determine the DQ. Patients with higher DQs preoperatively are found to have surgical outcomes better than those of children with lower DQs.^{25,153} Patients who undergo surgery as infants show the greatest improvement in DQ after surgery. The negative impact of persistent ETLE in children can therefore be appreciated by their poorer neurocognitive outcomes and decreased likelihood of recovery to appropriate developmental milestones in comparison with control patients.⁹⁸ Early surgery also improves behavioral disorders and psychosocial outcomes in certain cases of ETLE.^{154–156}

The location of seizures also appears to influence seizure outcomes. Meta-analysis of outcomes data from various ETLE surgical cases reveals a tendency for frontal lobe resections to have worse outcomes than posterior cerebral resections.¹⁴⁹ The worse outcomes in ETLE, in comparison with those in temporal lobe epilepsy, result from the involvement of eloquent cortex functioning in speech, language, sensorimotor processing, and vision.¹⁵⁰ It is not possible to resect large sections of cortex to eliminate an epileptogenic region, so that epileptic tissue is left behind to continue seizure propagation. Despite concern regarding the outcomes of surgery involving sensorimotor cortex, seizure freedom can be obtained in these cases.³² Approximately 77% of patients who underwent surgery for rolandic cortex seizures had an Engel I or II outcome, with minimal neurologic deficits at follow-up evaluation.

73.9.1 Frontal Lobe

Frontal lobe epilepsy is the most common ETLE in children and also has the worst reported seizure-free outcomes; this finding is related to several variables.¹⁵⁰ Seizure recurrence following surgery is more likely when patients have an MR-negative MCD, generalized or nonlocalized EEG patterns, acute postoperative seizures, or incomplete resections. Seizure-free rates 5 years following frontal lobectomy may be as low as 30%, and as low as 15% if the aforementioned negative prognostic factors are present.¹⁵⁷ In other reports, seizure-free rates vary from 50 to 65%^{8,158} in cases of frontal lobe epilepsy treated by lesionectomy. Complications of resection or of ongoing seizures can result in a frontal lobe syndrome of attention deficits, limited motor skills, behavioral abnormalities, and subtle changes in executive functioning. These results may be transient or, if they are related to persistent seizures, controlled with medication.^{159,160}

Neurocognitive outcomes following frontal lobe seizures can be difficult to assess because the degree of severity may not be fully appreciated until adolescence. Nevertheless, several studies have investigated the neurocognitive effects of ETLE surgery. Postoperative evaluation in children undergoing surgical intervention for epilepsy found that attention, as well as short- and long-term memory, were improved in comparison with a control group that had no surgery, although no significant differences in executive functions were noted.¹⁶⁰ Of interest, the benefits seen did not depend upon achievement of an Engel I outcome. Laterality of the surgery may impact outcomes, with left-sided resections causing word fluency problems whereas

right-sided surgery impairs fluency.¹⁶¹ The Engel I outcome correlates with improvement in short-term memory in postoperative patients. When the outcomes of children with frontal or temporal lobe epilepsy are compared, the children with frontal lobe seizures may have a decline in IQ postoperatively and a greater impairment in motor coordination, yet greater improvement in behavioral abnormalities.^{32,161,162}

73.9.2 Parietal Lobe

Parietal seizures account for the lowest percentage of pediatric epileptogenic activity, and the reported outcomes of children with parietal seizures are frequently linked to those of patients with seizures of occipital origin. Parietal lobe resections account for an estimated 4 to 14% of ETLE cases.¹⁶³ In mixed series of patients with epilepsy located in the posterior cortex, 40 to 72% had Engel I or II outcomes, with an estimated 35% having visual field defects postoperatively.^{37,163} Complications also included transient hemiparesis, aphasia, and somatosensory defects.³⁷ In addition, postoperative Gerstmann syndrome, with acalculia, right-left disorientation, finger agnosia, and agraphia, has been described after parietal lobe resections.¹⁶³ With limited surgical volume and experience in this area, the authors recommend tailored cortical resection based upon intraoperative ECoG or iEEG data.¹⁶³ Proximity to eloquent cortex precludes the complete resection of epileptogenic tissue in this region, and few diagnostic procedures have been linked to improved seizure-free outcomes for this location.³⁷ MSTs in the adjacent eloquent brain may be required to decrease seizure frequency or eliminate seizures.¹⁶³ In one of the few reports on neurocognitive outcomes in children who underwent parietal lobe epilepsy surgery, improvements in behavior and attention were identified, whereas cognitive functions remained unchanged.³⁵

73.9.3 Occipital Lobe

Extensive studies have reported outcomes following occipital surgery. It is estimated that upward of 60 to 68% of patients will have satisfactory Engel class I or II outcomes.^{43,164} Seizure outcome may depend on the concordance of diagnostic studies to localize the ictal focus.⁴³ MEG aids the resection of epileptogenic tissue, and the detection of dipoles in the contralateral occipital lobe³⁹ is associated with improved outcomes. Seizure outcome may also be related to a shorter duration of epilepsy.³⁶ A significant portion of patients will have a new or worsened visual field deficit after surgery, with 25 to 80% of patients in some series experiencing visual field changes.^{36,43} Some studies suggest that visual processing may be reorganized following surgery and that deficits may lessen as a consequence of neural plasticity.¹⁶⁵ The potential for recovery may be limited as a result of the early maturation of the posterior cortex. When patients are evaluated after the surgical resection of parietal or occipital lobe seizure foci, the recovery of visual perceptual cognition is limited, and it is possible that earlier surgery to reduce the degree of damage done to surrounding cortical circuitry can optimize cognitive outcomes in children. In the few reports of neurocognitive outcomes in patients with parietal and occipital lobe epilepsy, surgical resection appeared to improve verbal IQ more than performance IQ.¹⁶⁶ Although the numbers may be limited, 80% of the children achieved normal schooling levels.

Persistent deficits existed, however, in visual attention, object and facial recognition, and reading speed, which are functions subserved by the occipital and parietal regions of the cortex.

73.9.4 Neurocognitive Outcomes

Traditionally, children with behavioral issues or mental retardation have been viewed as less likely surgical candidates because these comorbidities are associated with a poorer prognosis.¹⁶⁷ A low preoperative IQ has also been reported as indicative of a poor surgical outcome because it may be related to diffuse cortical involvement.¹⁶⁸ As more contemporary studies expand the surgical indications for pediatric ETLE and the selection criteria for patients, the results hold promise of the inclusion of patients with lower IQs. Nearly 50% of children with an IQ below 70 had seizure freedom, whereas 68% of children with less severe retardation achieved seizure freedom.¹⁶⁹ Additional studies report seizure-free rates of 22 to 37% in children with an IQ below 70.¹⁷⁰ Although a lower IQ is a poor prognostic factor, there are children who can still benefit from surgical intervention. Persistent failures in patients with lower IQs may be attributable to a higher incidence of mixed seizures and diffuse cortical involvement. Despite these factors, palliative treatment options of corpus callosotomy and vagal nerve stimulation remain available, the benefits of which may not be seen until 1 to 2 years postoperatively.¹⁷¹

Neurocognitive outcome studies in children are needed to acquire future insight because the prevalence rates of behavioral, emotional, and socialization deficits are higher in children with epilepsy than in control populations.¹⁷² Despite reports in the adult literature, there remains a gap in the standardized reporting of outcomes in studies of pediatric ETLE.¹⁷³ One study that included children with ETLE revealed that the social interaction scores of children who had surgery improved, and that improvements continued to occur up to 2 years postoperatively.¹⁷² The greatest gains were seen in children with Engel I outcomes. Improvement may derive from a number of factors, including increased socialization with peers, parental acceptance of a seizure-free state, and recovery or plasticity in response to resolving IEDs. Although children are reported to have some improvement in outcome studies, they continue to experience deficits compared with controls.¹⁴ Neurocognitive abnormalities may persist as a result of a child's environment, which may include the continued use of anticonvulsant medications, persistent seizures if an Engel I outcome is not achieved, and persistent social stigmatization in classroom environments.¹⁷⁴

Although seizure freedom is the ultimate goal in pediatric ETLE, there are children possibly at risk for behavioral problems or poor performance who might benefit from the continued role of epilepsy surgery to prevent cognitive and developmental decline.¹⁷⁵ Defining successful outcomes when seizure freedom is not a realistic goal is a challenge for neurosurgeons treating pediatric ETLE. There is an expanding awareness that a reduction in the seizure burden, a stabilization of neurocognitive function, and a decrease in the overall requirement for medications may be secondary outcomes that significantly improve a child's quality of life and that of his or her family.¹⁷⁶ A case-by-case analysis is therefore warranted in a multidisciplinary setting to determine likely outcomes with the aforementioned

treatment approaches and to determine which cost–benefit analysis best suits an individual patient.

Throughout the literature, there is a lack of unanimity regarding preoperative assessment, diagnostic techniques, surgical techniques, and measures of outcomes in pediatric ETLE. Multicenter trials to pool patient data and coordinate clinical care strategies for these patients might be of benefit by clearly illuminating the paths toward improved outcomes and eliminating regional or institutional biases. Established centers have clearly paved the way for the multidisciplinary treatment of ETLE; however, future success requires that these centers coordinate their cost-effective and safe improvements in clinical care.

73.10 Conclusion

Extratemporal cortical resections play a large role in the treatment of medically refractory pediatric epilepsy, whereas adult epilepsy surgery commonly involves temporal resections. Two-stage procedures with invasive subdural and depth intracranial electrode arrays allow the localization of ictal onset and mapping of eloquent functions in nonlesional cases; they also may be helpful in lesional cases with discordant presurgical diagnostic data or a seizure onset near or within eloquent cortex. Although the developing brain is vulnerable to ongoing or re-mitting seizures that can stunt cognitive development, it also has a tremendous amount of plasticity that can result in surprisingly good neurologic recovery, even when eloquent cortex must be sacrificed. Ongoing advances in anatomical and metabolic imaging, functional localization, and surgical techniques, as well as improvements in patient selection and an increasing recognition of the value of neurocognitive testing and follow-up, are resulting in improved outcomes for an increasingly large number of children over time. All children with refractory epilepsy should be evaluated at a comprehensive epilepsy center to determine if they might benefit from the ever-increasing stable of nonsurgical and surgical options that are now available.

Pearls

- Multidisciplinary teams offer expertise and familiarity with a host of diverse pediatric extratemporal lobe etiologies.
- All children with medically refractory epilepsy should be referred to a pediatric epilepsy center for evaluation.
- A comprehensive presurgical consultation with patients and families helps to set realistic expectations and goals.
- Staged procedures with subdural grids and electrodes improve ictal localization when MR imaging and other preoperative studies are unsuccessful in identifying a lesion. Detailed ictal localization and functional cortical mapping are significant advantages seen with two-stage procedures.
- Neural plasticity in younger children can substantially mitigate early postoperative neurologic deficits.
- Maximal concordance between diagnostic studies may yield the best rates of seizure freedom.
- A more favorable prognosis can be expected after extratemporal resections when surgery is lesional, the ictal onset is focal, the diagnostic studies are concordant, and wide resections are performed.

74 Nonresective and Neuromodulatory Treatments of Refractory Epilepsy

Joseph R. Madsen, Jay D. Turner, and P. David Adelson

As many as 10 to 40% of pediatric patients with epilepsy have intractable seizures, despite the use of multiple antiepileptic agents.¹⁻³ Seizure control is especially important in the pediatric population because persistent seizures can profoundly impair cognitive and psychosocial development.^{4,5} In these patients, surgical intervention can be offered as an alternative means of seizure control.

Epilepsy is a diverse entity caused by a range of distinct pathologies. For this reason, multiple surgical interventions have emerged for the treatment of various disease processes. Beginning with Horsley's excision of neocortical tissue for focal motor seizures in 1886⁶ and the pioneering work of Foerster, Penfield, Jasper, and others, epilepsy surgeries have classically been resection procedures with the goal of removing or ablating epileptogenic tissue. These procedures include both focal resection (lesionectomy) when discrete anatomical lesions like neoplasms and vascular anomalies can be identified, and wider excisions (corticectomy, lobectomy, hemispherectomy) when the underlying pathology is more diffuse, as in malformations of cortical development and mesial temporal lobe sclerosis. The goal of resection procedures is curative, with the hope that removal of a presumed primary epileptogenic focus will prevent further seizures. These strategies of focal resection and their application in children are discussed in other chapters.

In many patients, resection is not a viable option, either because there is no clearly identifiable seizure focus, there are multiple diffuse epileptogenic foci, or an epileptogenic focus exists in nonresectable eloquent cortex. In such cases, nonresective interventions should be considered. Instead of the resection of epileptogenic tissue, the goal of these interventions is to modulate the existing circuits to control seizure initiation, propagation, and/or generalization. Nonresective treatments are generally palliative rather than curative, with the intended goal of reducing the frequency or severity of seizures. Two subtypes of procedures fall into this category of neuromodulation: disconnection procedures and neurostimulation. Disconnection procedures transect afferent and efferent fibers in an attempt to functionally isolate surrounding epileptogenic tissue—either directly or indirectly interrupting pathways that mediate excitation and seizure propagation from a primary focus, or disrupting more complex dynamics, such as subcortically mediated synchronization or network-level coupling, to prevent the generalization of pathologic synchronous neural activity. The mechanism of action of neurostimulation procedures is more complex. Generally speaking, an electrical stimulus is initiated to “modulate,” either directly or indirectly, through the excitation of excitatory or inhibitory pathways of the neural networks involved in epileptogenesis. We review here the most common nonresective neurosurgical strategies for intractable epilepsy, with a particular focus on corpus callosotomy and vagus nerve stimulation.

74.1 Disconnection Procedures for the Isolation of Epileptogenic Tissue

74.1.1 Multiple Subpial Transections

Multiple subpial transections (MSTs) were introduced by Morrell and colleagues for medically refractory partial epilepsy originating in eloquent regions of neocortex.⁷ The rationale for MSTs is based on the concept that normal neurophysiologic function relies primarily on vertically oriented fibers, independently of the lateral propagation of seizure activity. Transecting the cortex in the horizontal plane disrupts seizure spread while sparing normal function. Multiple retrospective studies have demonstrated that MSTs are safe and efficacious⁸⁻¹³; however, this has not yet been validated by a prospective trial.

To create MSTs, a fine microdissection device is introduced through the pia and is used to make vertical transections oriented perpendicularly to the long axis of a gyrus, with parallel transections repeated at approximately 5-mm intervals across the epileptogenic region. Postsurgical results reveal a generally excellent seizure response (60 to 70% patients achieved >95% reduction in seizure frequency in a recent international meta-analysis); the comparable responses for MSTs alone and the combination of MSTs plus resection in partial seizures validate the disconnection paradigm as a viable means of seizure control.¹⁴

74.1.2 Functional Hemispherectomy

Functional hemispherectomy (hemispherotomy) is analogous to MSTs in that it attempts to circumscribe and isolate an epileptogenic focus; however, the target region is an entire hemisphere rather than a single lesion, and the isolated neural circuits are completely disconnected from the rest of the brain. This procedure and several variants are modifications of the original hemispherectomy procedure,¹⁵ with the frontal and occipital poles left intact but disconnected to avoid the superficial cerebral hemosiderosis related to hemorrhage into the extended resection cavity.¹⁶ Functional hemispherectomy, which is discussed in Chapter 75, is different from the other disconnection procedures considered here in that there is no intention of preserving the function of the neurons left behind but disconnected.

74.1.3 Corpus Callosotomy

Division of the corpus callosum to prevent seizure generalization is the other major type of neurosurgical disconnection procedure. Corpus callosotomy has been shown to be safe and effective, with the greatest benefit for patients with intractable drop attacks and/or generalized tonic-clonic seizures.¹⁷⁻¹⁹

Dandy initially reported the feasibility of operative corpus callosum division after using this maneuver for pineal tumor resections.²⁰

Disconnection of the cerebral hemispheres to treat intractable seizures was then proposed by Van Wagenen and Herren soon thereafter,²¹ contemporaneously with pioneering work by Erickson on the effect of callosotomy on seizure propagation in the monkey.²² Although additional midline structures, including the interhemispheric commissures, massa intermedia, and fornix, have been the targets of disconnection procedures, there is no clear benefit beyond that of corpus callosotomy alone. Today, understanding is evolving about both the functional implications of corpus callosum division and the possible mechanisms of seizure control with corpus callosotomy.

Corpus Callosum: Anatomy and Function

The corpus callosum is the largest commissural connection in the human brain, consisting of an estimated 200 million interhemispheric fibers between primarily homologous areas of neocortex.²³ Most callosal fibers connect higher-order association areas, with only minimal callosal projections observed between primary motor or sensory cortices. Although the anatomical organization of the callosal fiber tracts is now well-established, the mechanisms mediating the transfer of information are still a topic of debate.²⁴ Many studies support an excitatory role, in which the corpus callosum allows the interhemispheric integration of information. Others suggest that callosal fibers impose an inhibitory effect on the opposite hemisphere, leading to increased lateralization and allowing more efficient processing.^{25,26}

Anatomically, the corpus callosum demonstrates a heterogeneity of fiber composition and connectivity that underlies its various physiologic functions. Despite their relatively sparse representation in the callosum, connections between primary and secondary sensorimotor regions comprise the majority of large-diameter myelinated callosal fibers in the primate brain.^{23,27} This distribution of fast-conducting fibers is consistent with hypotheses that fast interhemispheric processing via the corpus callosum mediates certain midline fusion tasks, such as central vision, depth perception, binaural sound localization, and aspects of bimanual coordination.²⁸⁻³¹ In contrast, interhemispheric connections between higher-order neocortical regions, such as the prefrontal cortex and extrastriate visual cortex, consist primarily of small-diameter unmyelinated fibers. Such slow-conducting fibers have been theorized to mediate the integration of more processed information between associative cortices.²⁷ There is also a generally rostral-to-caudal topography of callosal fibers corresponding roughly to the neocortical regions they interconnect: prefrontal fibers in the rostrum and genu; motor, somatosensory, superior temporal, and parietal fibers in the body; and inferior temporal and visual fibers in the splenium.^{32,33} Neurotracing studies suggest that the vast majority of these interhemispheric connections are homotopic, but heterotopic callosal fibers mediating interhemispheric parallel processing between different associative areas may also play a role.³⁴ Likely the addition of tractography with diffusion tensor imaging and improved functional imaging and electrophysiologic modalities will help to elucidate the functional aspects, circuitry, and networks delivered in communication through the corpus callosum.

Various animal and human models have been studied to better elucidate the function of the corpus callosum. Experiments in callosotomized animals first established a role for the corpus callosum in the somatosensory transmission of information between the hemispheres.³⁵ However, its involvement in more complex cognitive function required direct evaluation in human models and human pathologic conditions.

Congenital callosal agenesis has been extensively studied and has contributed to our current understanding of callosal function.^{36,37} However, these studies should be interpreted with caution because patients with congenital callosal agenesis often have other structural abnormalities (e.g., absence of the anterior commissure and hippocampal commissure).³⁸ Furthermore, with congenital absence of the callosum, reorganization and functional compensation likely occur, given the neural plasticity of the developing brain.³⁹⁻⁴¹ In contrast, the ability of the brain to compensate for lesions acquired postnatally is more limited.

The most meaningful functional data have been generated in human patients with a postsurgical split brain. Over the past 40 years, a growing neuropsychological literature has accumulated describing the effects of partial or complete callosotomy in patients with intractable epilepsy. In the cognitive nomenclature, the condition resulting from the callosotomy was termed *split brain*.⁴²⁻⁴⁴ The varying deficits and degrees of impairment seen after callosotomy indicate the subtle and diverse nature of callosal function. A characteristic acute neurologic syndrome occurs in the first few postoperative days and includes most frequently mutism as well as nondominant arm and leg apraxia, bilateral Babinski signs, and urinary incontinence.^{45,46} These complications are almost always transient (although left-sided apraxia can persist for weeks or in rare cases be permanent) and may result from intraoperative retraction and manipulation rather than callosal division.

Most of the persisting deficits following callosotomy involve the incomplete integration of information processing across hemispheres, often referred to in aggregate as the disconnection syndrome.⁴⁷ In general, these deficits are subtle, and controlled neuropsychological testing is often required to elicit them. There is limited interhemispheric transfer of unilaterally presented perceptual information, such as visual and shape information. After callosotomy, patients also show deficits in the temporal coupling of continuous (but not discrete) bimanual movements,²⁹ as well as difficulty in learning new tasks requiring bimanual cooperation.⁴⁸ However, previously learned bimanual tasks, such as playing the piano and tying shoelaces, are preserved, suggesting a callosal role in the initial integration of complex motor tasks before eventual transfer to subcortical and cerebellar structures. This is consistent with human studies showing interregional and interhemispheric coherence of electroencephalographic (EEG) signals across premotor and sensorimotor regions during the acquisition of bimanual tasks.⁴⁹ Language processing also exhibits deficits after callosotomy, which follows from the strong tendency of the human brain for lateralized language dominance. Images projected to the language-dominant left hemisphere (right visual field) can be easily described but cannot be verbalized when they are projected to the nondominant hemisphere despite their accurate reporting via nonverbal means (pointing).

Although many models support a transcallosal excitatory integration of information, there is evidence that some callosal

function may be inhibitory in nature. Activation of the motor cortex by a conditioning stimulus or direct electrical or transcranial magnetic stimulation causes inhibition of the contralateral motor cortex in animals and humans, likely via a transcallosally mediated activation of local inhibitory interneurons.^{50–52} After callosotomy, the normally unitary attention system can function as individual attentional processes,^{53,54} indicating a crucial role for the callosum in generating an integrated visuospatial attention system. Dual attentional processes may be prevented by interhemispheric inhibition in the normal brain, and the corpus callosum may have an integral role in generating selective attention. Tonic inhibitory processes are important to consider because disconnection procedures can produce a deafening of external inhibition to a region, which is a possible mechanism behind the occurrence of postoperative seizures.

Perhaps the most dramatic complication of callosotomy is the alien hand syndrome, which represents a disruption of perceived conscious will and volition.⁵⁵ Originally described by Goldstein in 1908 and further characterized by Akelaitis in 1945, patients with alien hand syndrome experience the subjective feeling of an upper limb performing complex motor acts outside their own volitional control.⁵⁶ In addition to the striking intermanual conflict that most vividly demonstrates the syndrome, other signs of alien hand syndrome include automatic mirror movements of the unaffected hand, enabling synkinesis, grasp reflex, magnetic apraxia or impulsive groping, and utilization behavior. Alien hand syndrome can be divided into cases arising from callosal pathology or unilateral lesions of the cortex, in which the “alien” hand is always contralateral to the lesion. In the “callosal” subtype, alien hand syndrome results from surgical transection, each with a signature symptomatology that results from damage to distinct anatomical structures.⁵⁷ The subtype of “callosal” alien hand syndrome results from surgical transection of the anterior corpus callosum or ischemia or rupture in the anterior cerebral artery circulation, presumably affecting fibers between premotor and motor areas. This subtype typically manifests as disrupted volitional control of the nondominant left hand. Although a relatively rare complication of callosotomy, the alien hand syndrome suggests that the corpus callosum participates in the construction of a unitary perception of “conscious will” by integrating either the performance of volitional action or the subjective perception of such behavior across hemispheres.

Corpus Callosotomy: Mechanism of Seizure Prevention

The goal of corpus callosotomy is the palliative treatment of intractable generalized seizures, but the physiologic mechanism of seizure control produced by the division of callosal fibers remains unclear. The initial rationale behind callosotomy for seizure control was that the interruption of transcallosal pathways would prevent interhemispheric synaptic activation and seizure propagation. However, more recent evidence suggests that the callosal role in epileptogenesis may be more complex. In some studies of EEG changes after callosotomy, preoperative bilaterally synchronous epileptiform discharges are transformed into primarily lateralized or asynchronous ones, suggesting a callosally mediated propagation of seizure activity from one hemisphere to another.^{58–60} However, other evidence supports a

mechanism involving an overall decrease in cortical epileptogenicity rather than an interruption of propagation pathways; callosotomy can produce a reduction in seizure severity and frequency without a transformation from generalized to partial seizures or, in some cases, complete suppression of seizure activity.^{14,58,61,62} Furthermore, in an intraoperative study of callosal compound action potentials and bilateral spike-and-wave discharges in epileptic patients, interhemispheric delay times were often less than the minimum axonal conduction time (approximately 20 milliseconds), and callosal compound action potentials peaked after their associated spike-and-wave complexes.⁶³

In addition to the direct transfer of synchronous seizure activity, other mechanisms of corpus callosum-mediated modulation of epileptogenesis have been proposed. One hypothesis is that both hemispheres are capable of generating epileptiform discharges and that the corpus callosum provides a pathway for the synchronization rather than the transfer of activity.⁶⁴ Consistent with facilitation via the corpus callosum, repetitive transcallosal volleys at 5 to 20 Hz enhance cortical reactivity as measured by thalamocortical responses in a rat model, an effect suppressed by callosotomy.⁶⁵ It should be noted that callosal pathways are not required for seizure generalization; patients with Aicardi syndrome have congenital agenesis of the corpus callosum yet exhibit infantile spasms in addition to ocular abnormalities and mental retardation.⁶⁶ In these patients, callosal pathways cannot mediate the propagation of synchronous activity from a lateralized focus, suggesting that seizure generalization must occur via other interhemispheric or subcortical tracts. From a wealth of animal studies, it appears that cortical and thalamic networks involved in physiologic sleep oscillations are critical in generating the spike-and-wave and polyspike-and-wave complexes seen in certain generalized epilepsies, such as absence epilepsy and Lennox-Gastaut syndrome.⁶⁷ A growing understanding of the behavior of interconnected networks indicates that the dynamic, oscillatory behavior of such systems is dependent on their topology, scale, and connectivity.⁶⁸ The corpus callosum may comprise critical internodal connections of hemispheric thalamocortical circuits that provide the necessary dynamic system to generate generalized synchronous ictal activity.

Corpus Callosotomy: Outcomes

Corpus callosotomy has been demonstrated to be effective in the treatment of generalized seizures since as early as 1940.¹⁷ Multiple retrospective series show a reduction of generalized seizures after corpus callosotomy, with response rates ranging from 56 to 100%.^{61,69–72} The best and most consistent responses are seen in patients with drop attack seizures of tonic, atonic, or mixed type, with response rates approaching 100% in some studies.^{18,71,73,74} Similar response rates are seen in pediatric series,^{69,75,76} and callosotomy reduces medically refractory seizures in specific pediatric epilepsies such as the West and Lennox-Gastaut syndromes.⁷⁷ In pediatric cases, an examination of parental satisfaction showed a high level of reported satisfaction with surgical outcome (88%), although interestingly satisfaction was not strongly correlated with measured seizure reduction and might have been related to behavioral changes, such as improved alertness and responsiveness.⁷⁸ Reduction in seizure

frequency is also correlated with perceived changes in quality of life, with improvements in self-care, family life, and school performance.⁷⁹

Although the efficacy of corpus callosotomy for drop attacks is generally well accepted, the factors that contribute to a favorable outcome have been a topic of debate. There has been significant variation in the extent of callosal division used to achieve seizure control. Several studies have demonstrated that total corpus callosotomy is more efficacious and durable than partial divisions in the treatment of drop attacks.^{17,18,70,71,80–82} In general, better results are achieved with greater extents of resection, and often clinical algorithms can be developed for recommending a complete callosotomy in children who have severe underlying cognitive dysfunction or language impairment. Partial callosotomy limited to the anterior two-thirds of the callosum can provide some degree of palliation in children with good cognition and language as a first stage, but incremental benefit can still be gained with the conversion of partial procedures to total divisions if seizures continue.^{70,77} Recognition of an increased risk for disconnection syndrome after the disruption of posterior callosal fibers, either alone or as part of total callosotomy,⁷² led to the development of a two-stage procedure in which an initial anterior callosotomy is followed by a 6- to 12-month evaluation period to determine effectiveness before optional conversion to total resection.⁷⁰ In terms of reduction of seizures, there are no observed differences between children and adults, and the outcome of either anterior or total callosotomy is not related to age at the time of surgery. Efforts to identify EEG predictors of responsiveness suggest that lateralized changes in interictal EEG can predict a good outcome of callosotomy,⁷¹ although specific patterns of ictal EEG activity may be a stronger prognostic factor.⁸³ Other factors that may portend a favorable outcome include the absence of abnormality on magnetic resonance (MR) imaging and the absence of identified seizure etiology.⁸⁴

Significant adverse effects are relatively rare with callosotomy, and standard neuropsychological and psychosocial assessments generally reveal little change compared with the pre-morbid condition.⁴⁵ A precise characterization of neuropsychological effects is difficult; many patients have preexisting developmental delay, frequent seizures, and multiple antiepileptic drug regimens, and effective seizure control often can improve testing results. A characteristic acute postoperative neurologic syndrome is observed with mutism, nondominant arm and leg apraxia, bilateral Babinski signs, and urinary incontinence.^{45,46} These complications are almost always transient, with the mutism resolving typically within several weeks, and evidence suggests that intraoperative retraction and manipulation, rather than callosal division, may be the cause.

Permanent side effects of callosotomy are relatively rare, with weakness or apraxia and impairment of language and behavior occurring in 8% of partial and 12% of total callosotomies.⁸⁵ After callosotomy, dysphasia is seen specifically in patients with mixed or crossed cerebral dominance, in whom the language-dominant hemisphere does not control the dominant hand⁸⁶; specifically, dysgraphia and dysphasia were seen in crossed-dominant right-handed patients, and dysgraphia alone was seen in crossed-dominant left-handed patients. Sensory disconnection resulting from the division of posterior callosal fibers is well documented, but the effects are subtle, and controlled

neuropsychological testing is often required to identify it (see above). Disruption of the interhemispheric integration of motor information makes it more difficult for patients who have undergone a callosotomy to learn new bimanual tasks,⁴⁸ but previously acquired bimanual tasks remain intact. Memory deficits are noted in a small subset of cases and may represent either preexisting extracallosal damage to structures like the fornix or extensive posterior callosal sections affecting the hippocampal commissures.^{87–89}

Corpus Callosotomy: Surgical Technique

Anterior callosotomy and single-stage complete corpus callosotomy are performed with the patient under general anesthesia. The patient is in the supine position, with the head elevated and very slightly flexed. Typically, we prefer a simple linear incision 2.5 cm in front of the coronal suture, extending from 3 cm to the left of midline to 7 cm to the right of midline, directly perpendicular to the midsagittal line (► Fig. 74.1). Two bur holes are placed right on the midline. One is at the bregma, the confluence of the coronal and sagittal sutures, or no more than 1 cm posterior to this point. The other is placed 5 cm anterior to the bregma, again directly at or just left of midline. To achieve adequate midline visualization along the corpus callosum, it is necessary that the bone flap come exactly to the midline or even slightly to the left of midline. The careful placement of bur holes directly over the sagittal sinus has proved to be a safe practice, but to avoid potential injury or any difficulty with midline visualization, the authors place the bur holes and the edge of the craniotomy slightly to the *left* of the sinus to avoid obstruction of the view by overhanging bone or injury to the sinus. A trapezoidal or D-shaped craniotomy that is 5 cm long is made with a high-speed drill.

The dural opening needs to be only 1.5 to 2 cm from the edge of the sagittal sinus and parallel to it. There are often bridging veins at the level of the coronal suture that require care in preservation as this dural opening is made. Venous lakes in the region also sometimes have to be oversewn. Although an experienced operator can visualize the entire corpus callosum through a smaller bone opening, we prefer approximately 5 cm of exposure here anterior to the coronal suture to provide flexibility in circumventing any bridging veins. Careful analysis of the vascular anatomy on MR imaging can be helpful in preparing for venous structures that may be encountered.

After the dura is opened, the right frontal lobe is gently retracted away from the falx under the microscope. Fixed retraction is avoided on the brain itself but can be applied to the falx side if necessary. There are occasionally significant arachnoidal adhesions, and below the lower limit of the falx there are almost always adhesions between the two cingulate gyri. Microscopic dissection is used to divide the arachnoidal adhesions. It is important not to mistake the callosal marginal arteries for the pericallosal arteries and therefore mistake cingulate gyrus for corpus callosum. The corpus callosum is significantly whiter and smoother than the cingulate gyrus, and generally one or both pericallosal arteries come into view at the same time as the corpus callosum.

Next begins the phase of dissecting between the two pericallosal arteries to expose the corpus callosum over the entire length of the needed visualization. Usually, there is no doubt

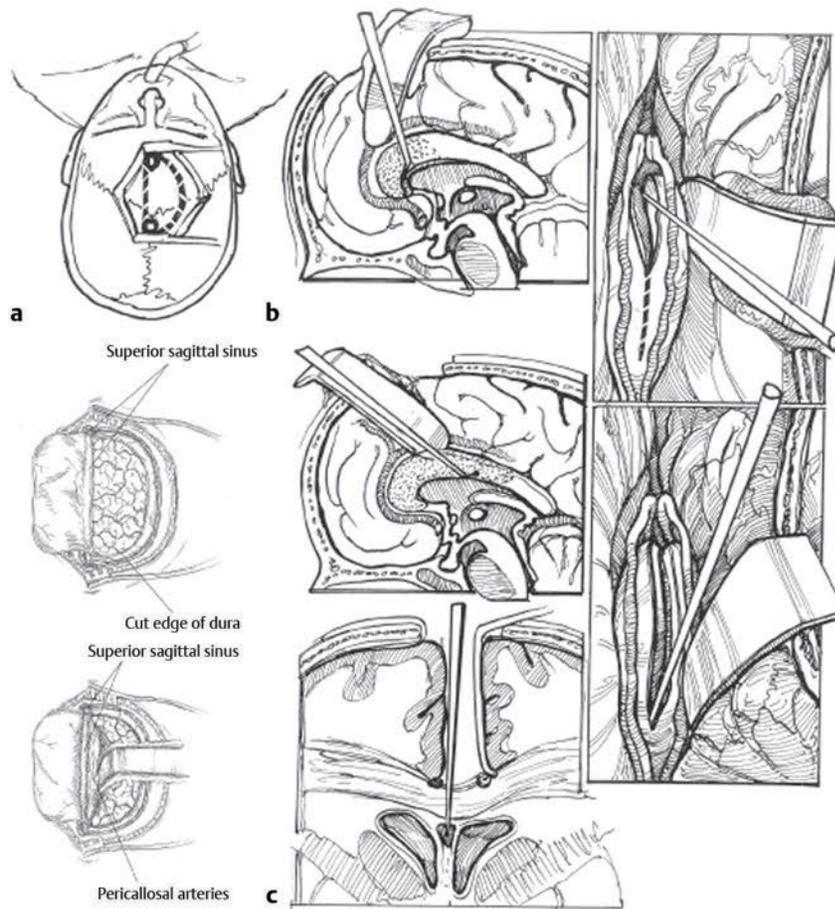

Fig. 74.1 (a) The child is positioned with the neck slightly flexed and the forehead toward the ceiling. A straight coronal incision 3 cm in front of the coronal suture permits a tight-shaped skull exposure. The craniotomy, in the shape of a large letter D, is begun with bur holes over the sagittal sinus just behind the coronal suture 6 cm in front of it. The left edge of this opening is just to the left of the sagittal sinus. (b) The placement of retractors through this precoronal bone flap allows exposure of the entire corpus callosum. Once the midline has been determined by identification of the raphe between the two ventricles, removal of the commissure or white matter can proceed rapidly anteriorly and posteriorly. The use of a microdissector passed just posterior to the anterior cerebral arteries allows the genu of the corpus callosum to be completely sectioned. This exposure also allows estimation of a point approximately two-thirds back in anterior corpus callosotomy (stippled area). (c) Detail of a ball-tipped micro nerve hook in the cavum vergae space that keeps the corpus callosum division on midline and prevents straying in either lateral ventricle.

about which pericallosal artery is the right and which is the left, but if there is any variation from normal anatomy, it can be deciphered at this time by following small branches off these arteries either to the right or to the left. It is almost always worthwhile to dissect the two arteries apart so that the actual callosotomy can be made between them. If this is not possible without significant manipulation of the artery, it can also be arranged to do the callosotomy on one side or the other of both of the arteries, but this generally makes it more difficult to stay on the true midline as the artery crosses back and forth over the surgical field.

Once the corpus callosum is well exposed from the genu to the body and the splenium, the desired posterior margin of the callosotomy can be determined through visual inspection and direct measurement and/or image guidance. The corpus callosum is entered in the midline at the level of the coronal suture (► Fig. 74.2). Even in a patient without a cavum septum evident on MR imaging, there is usually a small space between the two medial surfaces of the lateral ventricle and the corpus callosum, and the goal on coming through the corpus callosum is to enter through to this space, leaving the ependyma intact so as not to enter into the ventricle. Avoiding entry into the ventricles and preserving the ependyma significantly decreases complications related to intraventricular hemorrhage (including chemical meningitis and hydrocephalus). The midline is sometimes marked with a small vein, and when present this can be used as an anatomical guide. If there is inadvertent deviation from

midline, the ependyma may come into view; it appears as a translucent layer with dark-appearing underlying ventricular fluid. If deviated from midline, effort should be made to explore slightly to the right and left to find this midline raphe. Once the raphe is located, a small, ball-tipped microdissector can be inserted into it, and this can be used to pull the corpus callosum up from below toward the aspirating sucker, dissecting forward toward the genu first and then posteriorly to the splenium later. It is generally possible to stay out of the ventricle entirely by using this maneuver. However, if the ependyma is breached, a small piece of collagen pad can be placed over the opening to prevent intraventricular passage of blood and debris. The callosotomy is continued anteriorly in the same plane into the genu, following the pathway and orientation of the pericallosal arteries. Once the anterior cerebral arteries are identified on the anterior aspect of the genu, the callosotomy can be safely continued all the way to the anterior communicating artery complex to the level of the anterior commissure, which is visible and deep and posterior to the genu at this point of the dissection.

The decision about the posterior extent of disconnection is planned preoperatively based on the review of the sagittal MRI. The length of disconnection, measured from the anterior tip of the genu, is about two-thirds the length of the total corpus and avoids sectioning of the splenium. Image guidance techniques can be very useful in gauging the distance back on the corpus callosum in anterior callosotomy to avoid inserting modified disposable rulers or patties. The disconnection then proceeds

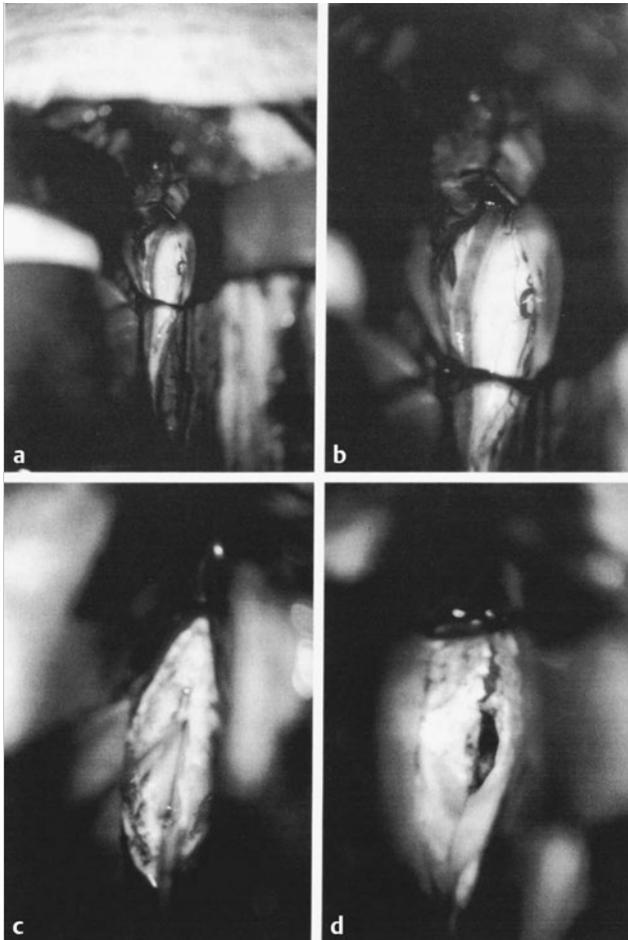

Fig. 74.2 Photographs through the operating microscope show exposure of the corpus callosum and identification of the midline raphe with corpus callosum division, as described. (a) Low-magnification and (b) higher-magnification views of the approach to the corpus callosum, which is distinctly whiter than the abutting cingulate cortex. (c) Aspiration of the callosal white matter shows the midline raphe between the ventricles, at the floor of the cavum vergae. Complete removal of the callosal fibers is ensured by proceeding forward with the ball-tipped micro nerve hook just above the raphe. (d) Further forward, the raphe falls away as the corpus callosum curves around the genu. The passage of a dissector between the superior part of the callosal fibers and the arachnoid allows the genu to be pulled posteriorly and divided, with direct visualization of the arachnoid down to the region of the anterior communicating artery complex.

posteriorly with the same technique used in the anterior division. After adjustment of the patient's position head down with a small amount of Trendelenburg and of the angle of the microscope, the midline cleft between the ventricles is followed posteriorly to maintain a midline position and avoid injury to the corona radiata on either side of the corpus callosum. The cleft usually blurs posteriorly as the ventricles diverge from each other to the atria and then the temporal horns. The midline, though, can still be followed, and the posterior margin of the splenium (in the case of a total callosotomy) can be visualized. The callosotomy is completed through the splenium to the posterior commissure, with the arachnoid surrounding the vein of Galen left intact.

After completion of the callosotomy, hemostasis is meticulously achieved. A piece of collagen pad is cut to the appropriate size and positioned in the callosotomy defect. The dura is then reapproximated, the bone flap replaced, and the wound closed with standard technique.

74.2 Neurostimulation

Electrical stimulation for the treatment of seizures can be applied to various targets within the central and peripheral nervous systems. The goal of neurostimulation is to inhibit epileptogenicity; however, the mechanisms of action are poorly understood. Both open-loop and closed-loop systems are used for neurostimulation. Deep brain stimulation (DBS) and vagus nerve stimulation (VNS) are the two open-loop systems most commonly employed, in which continuous stimulation is applied according to set algorithms without regard to whether the patient is having a seizure or not. In contrast, closed-loop applications, such as regional neurostimulation (RNS), provide acute stimulation only when abnormal electrical activity is detected.^{90–92} The closed-loop algorithms required to detect the ictal state, as well as the electrical stimulation parameters necessary for seizure termination in both open- and closed-loop systems, are areas of active research.^{93–95}

74.2.1 Regional Neurostimulation

Closed-loop systems are dynamic circuits that use real-time feedback to deliver stimulation to a specific areas, either to the area of an epileptic focus or through circuit networks shared by the focus, only in a time of anticipated need. As a self-modulating system, RNS has the potential for tremendous sophistication. In its current state, RNS is of limited utility and can be applied only to definable epileptic foci. Fairly simple algorithms are used for RNS execution. Nonetheless, the techniques used for the detection of ictal activity and the delivery of electrical stimulation are areas of active research, and this is a technology that will certainly continue to evolve.^{93–95} Current evidence suggests that changes in the dynamics of electrical activity can be detected well before the development of seizures,⁹⁰ thus allowing earlier stimulation and potentially more effective treatment.

74.2.2 Deep Brain Stimulation

In contrast to a closed-loop system, an open-loop system like DBS applies continuous stimulation to deep brain nuclei without reference to the brain's electrical activity. A wide variety of targets for the treatment of refractory seizures have been evaluated and include the cerebellum, basal ganglia, subthalamic nucleus, and thalamus (centromedian, anterior thalamic nuclei).^{96–101} Although the results of many of the studies show promise, definitive conclusions are often prohibited by small patient populations and a lack of long-term follow-up. Stimulation of the anterior thalamus, on the other hand, has been thoroughly studied. The randomized controlled SANTE (Stimulation of the Anterior Nucleus of the Thalamus for Epilepsy) trial demonstrated a median rate of seizure reduction of 56% by 2 years and a higher than 50% rate of seizure reduction in 54% of patients with medically refractory partial seizures.¹⁰² During the blinded phase of the study, patients with temporal lobe

seizures showed a greater benefit than with those with extra-temporal or multifocal seizure onsets.

74.2.3 Vagus Nerve Stimulation

The prototypic neurostimulation procedure for epilepsy—and the only antiepileptic stimulation treatment currently approved by the Food and Drug Administration (FDA)—is VNS. VNS was first attempted in a human patient in 1988¹⁰³ and was approved by the FDA in 1997 as an adjunctive treatment for medically refractory partial-onset epilepsy. The rationale for the intermittent unilateral stimulation of the cervical portion of the vagus nerve is based on the long-standing observation in laboratory animals that vagal stimulation produces EEG cortical desynchronization.^{104,105} A growing body of literature demonstrates that VNS is a safe, well-tolerated, and efficacious palliative treatment for both partial-onset and generalized medically refractory epilepsies.

Vagus Nerve Anatomy and Physiology

The vagus nerve (cranial nerve X) is a mixed motor and sensory nerve. Its wandering innervation extends from the medulla to the splenic flexure of the colon. Efferent fibers comprise only 20% the vagus nerve, carrying branchial motor efferents to the larynx and pharynx and parasympathetic visceral efferents to the pharynx, larynx, and organs of the thorax and abdomen.¹⁰⁶ The remaining 80% of the vagus nerve carries primarily visceral afferent fibers from the neck, thorax, and abdomen and from stretch receptors in the aortic arch and chemoreceptors in the carotid bodies; a small proportion of fibers also carry somatic sensory (external auditory meatus, tympanic membrane) and special sensory (taste) afferents. Asymmetric development leads to an association of the right vagus nerve with the cardiac atria and of the left vagus nerve with the cardiac ventricles, with relatively less dense vagal innervation of the ventricles.¹⁰⁷ This asymmetric cardiac innervation is the likely reason why unilateral stimulation of the left vagus nerve minimizes cardiovascular side effects in humans.

Vagus nerve fibers distribute widely through the central nervous system, both monosynaptically and through the nucleus of the solitary tract (NTS).¹⁰⁸ Although a small number of fibers connect directly to the spinal trigeminal nucleus and the reticular formation, the vast majority of vagal afferents are carried to the NTS via sensory neurons of the nodose ganglion. Three major output pathways distribute afferent vagal information from the NTS to dispersed central nervous system structures.^{109,110} The first pathway mediates feedback control of the heart rate (baroreceptor reflex) and respiration (Hering-Breuer reflex) via autonomic preganglionic and somatic motor neurons in the medulla and spinal cord, while the second pathway targets the reticular formation of the medulla and controls autonomic and respiratory reflexes.^{111,112} The third major NTS output pathway projects to forebrain structures via the parabrachial nucleus of the dorsal pons and is the most likely mediator of VNS anticonvulsant activity. The parabrachial nucleus has widespread projections to the insular, infralimbic, and lateral frontal cortex, as well as to the thalamus, hypothalamus, amygdala, and basal forebrain.¹¹³ Via the amygdala, output pathways from the NTS project to other limbic structures

including the hippocampus and entorhinal cortex. Notably, there is direct parabrachial input to the intralaminar and midline nuclei of the thalamus, which project widely throughout the cerebral cortex and may influence both physiologic and pathologic cortical synchronization.^{114,115}

Most cerebral structures are three or more synapses away from the vagus nerve; this relatively large distance between the brainstem vagal afferent system and the different cortical sites of epileptogenesis responsive to VNS suggests a role for systems projecting diffusely between the brainstem and forebrain. Various anatomical pathways are activated during VNS, but the specific circuitry responsible for anticonvulsant activity and the nature of the neurophysiologic changes (e.g., increased vs. decreased activity) remain unknown. Examination of *fos* gene product expression following brief intermittent VNS in rodents showed elevated neuronal activity in the amygdala and limbic neocortex (cingulate and retrosplenial cortex), both of which are implicated in epileptogenesis, as well as in hypothalamic and noradrenergic nuclei.¹¹⁶ Positron emission tomography (PET) neuroimaging studies have shown acute increases in regional cerebral blood flow to the medulla, right postcentral gyrus, and bilateral thalamus, hypothalamus, and insular cortex during VNS, with deactivation bilaterally in the hippocampus, amygdala, and posterior cingulate gyrus.¹¹⁷ A higher level of stimulation affected the same structures as the low-level stimulation, but with increased volumes of activation and deactivation, and additionally activated the bilateral orbitofrontal gyrus, right entorhinal cortex, and right temporal pole. In follow-up PET studies, only left and right thalamic activation was correlated with decreased seizure frequency after 3 months of VNS.¹¹⁸ More recently, functional MR imaging (fMRI) during VNS demonstrated robust activation of the thalamus and insular cortex, with post-VNS seizure reduction also associated with thalamic activation.^{119,120}

Vagus Nerve Stimulation: Mechanism of Seizure Prevention

The diffuse cortical effects of VNS can be observed on the EEG, as in the early studies, which showed cortical desynchronization in cats after cervical VNS.^{104,105} Animal studies further demonstrated that repetitive vagal stimulation can induce either synchronization or desynchronization of the EEG, depending on stimulation frequency and current strength.^{105,121,122} Specifically, high-frequency NTS stimulation (>30 Hz) induces EEG desynchronization, whereas slower stimulation (<17 Hz) induces synchronization.¹²³ This preferential induction of synchronization with lower-intensity and slower-frequency stimulation and desynchronization with higher-intensity and faster-frequency stimulation may result from the differential recruitment of vagal afferent fibers, with desynchronization requiring activation of smaller-diameter unmyelinated fibers. In contrast, VNS in humans does not generally produce obvious or readily observable synchronization or desynchronization of the EEG.^{124,125} VNS produces evoked potentials of cerebral origin in scalp EEG only at stimulation intensities higher than those used clinically,^{126,127} but there is evidence that chronic VNS results in altered somatosensory and visual evoked potentials, which presumably reflect long-term changes in underlying neural circuitry.^{128,129}

In addition to its effect on the underlying physiologic EEG, VNS has observable effects on pathologic interictal epileptiform

discharges and seizure-like activity. The frequency of penicillin-induced focal interictal spikes in a rodent model of acute epilepsy is reduced 33% during VNS, an effect that can persist for minutes after the termination of electrical stimulation.¹³⁰ VNS has similar abortive effects on acute chemically induced seizures in rodent and canine models, an effect dependent on the activation of unmyelinated vagal C fibers.^{130–132} Although VNS in humans produces no observable changes in the interictal scalp EEG,¹²⁴ interictal epileptiform sharp waves recorded with hippocampal depth electrodes were decreased by 30-Hz vagal stimulation and increased by 5-Hz stimulation in a case report.¹³³ VNS also has acute prophylactic anticonvulsant effects that extend beyond the duration of stimulation, decreasing the number and duration of pentylenetetrazol-induced seizures in rats for up to 10 minutes after the termination of stimulation.¹³⁴ Furthermore, the prophylactic anticonvulsant effect of chronic VNS is progressive; chronic vagal stimulation over weeks is accompanied by decreasing seizure activity in an alumina gel primate model,¹³⁵ and longer-term VNS (up to 12 months) in human patients induces initial clustering of EEG epileptiform activity followed by progressively increased spike-free intervals.¹³⁶

Despite accumulating data, the precise mechanism underlying VNS-mediated anticonvulsant activity remains poorly understood. Antiepileptic drugs exert their effect through the modulation of voltage-dependent sodium and calcium currents and γ -aminobutyric acid (GABA)-mediated inhibition.^{137,138} Whereas antiepileptic drugs function by directly modulating cellular signaling on a molecular level, VNS functions through the stimulation of widely projecting brainstem pathways, which may result in the activation or inhibition of target regions. Thalamic nuclei are likely involved, given their consistent activation in PET and fMRI studies, the correlation between thalamic activation and seizure reduction, the diffuse nature of thalamocortical projections, and their role in physiologic and pathologic cortical synchronization.^{67,115,139} Noradrenergic activity also may be central to VNS function; noradrenergic nuclei show increase *fos* expression following VNS,¹¹⁶ and chemical lesion of the locus ceruleus significantly attenuates VNS-induced seizure suppression in rats.¹⁴⁰ In VNS-implanted rats, it has been demonstrated that stimulation increases norepinephrine concentration in the prefrontal cortex.¹⁴¹ Other associated biochemical changes include increased expression of brain-derived neurotrophic factor (BDNF) and fibroblast growth factor (FGF) in the hippocampus and cerebral cortex, and decreased expression of nerve growth factor in the hippocampus. It has also been postulated that VNS affects seizure thresholds by modulating inhibitory neurotransmission; chronic VNS is associated with increased cerebrospinal fluid levels of the inhibitory neurotransmitter GABA, but these changes were not correlated to the degree of seizure reduction.¹⁴²

Vagus Nerve Stimulation: Outcomes

VNS has been shown to be effective in managing both partial and generalized seizures, with the primary indicator of efficacy being a reduction of seizure frequency.^{143–145} In the multicenter randomized double-blinded controlled EO3 and EO5 studies, patients with medically refractory partial-onset seizures were implanted with a VNS system and received either a high-stimulation (30 Hz, 30 seconds on, 5 minutes off, 500- μ s pulse width)

or a low-stimulation (1 Hz, 30 seconds on, 90 to 180 minutes off, 130- μ s pulse width) protocol for 12 weeks. Patients receiving the higher-stimulation treatment experienced mean reductions in seizure frequency of 24.5% and 28% in the two studies, compared with 6.1% and 15% in patients receiving the lower-stimulation protocol, but both the high- and the low-stimulation treatment produced statistically and clinically significant seizure decrement. In a nonrandomized treatment trial of 24 patients, VNS also reduced the frequency of generalized seizures by 46% after 3 months of stimulation.¹⁴⁴

Although the current FDA indication for VNS covers patients 12 years and older, clinical data suggest that VNS has efficacy in younger pediatric patients as well. A study of 60 patients age 3 to 18 years (median age, 15 years; 16 patients younger than 12 years) demonstrated a 23% median decrease in seizure frequency after 3 months of stimulation, with a progressive benefit of continuing stimulation (31%, 34%, and 42% at 6, 12, and 18 months, respectively); patients had either partial or generalized tonic-clonic seizures (27%), and the response rate was not specific to seizure type.¹⁴⁶ Likewise, an uncontrolled retrospective study of patients between 11 months and 16 years of age with complex partial or generalized (atonic, absence, tonic-clonic) seizures reported improvements in seizure reduction regardless of age and seizure type.¹⁴⁷ VNS has also been used successfully to manage patients with Lennox-Gastaut syndrome. In 13 patients with Lennox-Gastaut syndrome (4 to 44 years of age), 6 months of VNS produced a 52% median reduction in seizure frequency, including 3 patients with a decrease of more than 90%.¹⁴⁸ In a smaller study of pediatric patients with epileptic encephalopathies, there was a greater than 50% reduction of seizure frequency in 4 (27%) of 15 patients, and a significant improvement in perceived treatment side effects and general behavior was noted, although no significant group improvement in seizure frequency or severity, adaptive behavior, or EEG.¹⁴⁹ In a recent randomized controlled study of 41 children with intractable epilepsy (35 with localization-related epilepsy and 6 with generalized epilepsy), VNS reduced seizure frequency by 50% or more in 26% of participants.¹⁵⁰

In general, VNS has proved to be safe and well tolerated.^{151–153} The most commonly reported side effects include dysphonia (20%) and cough (6%), which most often occur during the stimulation phases and resolve during the quiescent phase of the stimulatory algorithm.⁸ In the randomized double-blinded EO3 and EO5 studies, only voice alteration was more frequent in the high-stimulation than in the low-stimulation population; less common adverse effects included throat pain, nonspecific pain, dyspnea, paresthesias, dyspepsia, vomiting, and infection, with adverse effects in these two studies rated mild or moderate 99% of the time and with no observed negative impact on cognition, affect, or coordination.^{143,145} The impact of VNS on mood and cognition was looked at more closely in a recent randomized clinical trial.¹⁵⁴ Consistent with studies supporting a role of VNS for treatment-resistant depression, the authors found that VNS not only did not negatively impact mood or behavior but also led to a generalized improvement in mood for the entire group. The observed benefit was unrelated to the effect on seizure frequency. Furthermore, there is a low rate of surgical complications, with device failure (2.7%) and deep infection (3.5%) the most commonly observed in a retrospective study of pediatric patients undergoing device implantation.¹⁵⁵ One of the authors (P.D.A.) has had less than a 2%

incidence of infection and only a 0.4% incidence of deep infection requiring removal of the device. Erosion of the pulse generator through the chest wall can be a concern in children or debilitated patients with little subcutaneous fat but is a relatively rare occurrence that can be avoided with a subpectoral implantation. Furthermore, the next generations of devices are thinner and smaller, making this even less of an issue.

Cardiovascular adverse effects are a theoretical concern given the cardiac efferents from the vagus nerve, but significant cardiac complications have not been observed with VNS. A small number of cases have been reported of transient bradycardia or ventricular asystole during intraoperative testing of the device leads (estimated occurrence rate of 0.1%); proper caution dictates the use of test stimulation before generator implantation and close cardiac monitoring during the procedure.^{156,157} Despite the variable effects on cardiac rhythm observed during stimulation,¹⁵⁸ studies reveal no long-term cardiovascular effects involving arrhythmia or heart failure.

Vagus Nerve Stimulation: Presurgical Counseling

During the preoperative visit, we have found it useful to address expectations and counsel families that the therapeutic response to VNS is difficult to predict. The median response is an approximately 50% reduction in seizures, but a wide spectrum has been reported, and responses can be better or worse. In terms of patient selection, it is critical that the neurosurgeon first ensure that the patient does not qualify for more definitive, potentially curable procedures, such as focal resection, because VNS is merely a palliative therapy. It is also important that certain diagnostic studies, such as high-field-strength MR imaging, which requires the body magnet to send or receive signal, and magnetoencephalography, may not be possible in many centers after the VNS device is inserted. If these tests are important as part of the continued work-up or ongoing evaluation, steps to schedule them before the actual implantation should perhaps be considered. Other parts of the diagnostic work-up, such as routine head coil MR imaging and EEG, and even invasive monitoring, can be done with the VNS device in place and functioning if necessary.

Vagus Nerve Stimulation: Surgical Technique

Although several variations have been developed for placement of the VNS device, virtually the only absolutely necessary steps are to ensure that the electrode leads contact the correct nerve in the correct vertical orientation, and that the post-generator device be accessible to the patient for magnet activation and to the physician for reprogramming.

In the initial descriptions of the procedures,^{116,117} a vertical incision over the carotid sheath was described, and a horizontal incision more than 4 cm below the clavicle for placement of the device was suggested. Improvements to increase comfort and cosmetic appearance after ultimate placement of the VNS device have been developed subsequently over the years. Examples include the use of a single longer incision both to access the nerve and to make a pocket for the device on the chest or lateral pectoral incision.¹¹⁸

We have found that the most satisfactory approach in children is begun by making both incisions in the direction of skin

creases, which tends to minimize the amount of widening of the incision and gives a better overall cosmetic result (► Fig. 74.3). It also becomes possible to use incisions that are quite limited (as little as 2 cm in the neck and 2.5 cm in the axillary region), and to place the device under the pectoralis muscle rather than over the pectoralis muscle, particularly in very young or very thin patients. Most patients have adequate subcutaneous tissue to hide and cushion the device, especially with the newer small generators (Model 103 and beyond). Because the generation of a subcutaneous pocket is relatively trivial and the creation of a subpectoral pocket is more common in pediatric than in adult practice, this description focuses on subpectoral placement.

For the optimal placement of the device deep to the pectoralis muscle, it is important that the incision that gives access to this region be lateral and inferior to the margin of the pectoralis itself. For this, surgical scrub preparation of the axillary region and the rectangle extending up to include the anterior neck must be done. Typically, for the placement of a new device, we elevate the left side of the chest, abduct the shoulder slightly, and keep the left arm flexed somewhat, so that the arm falls out of the way of the access to the subpectoral region. The neck is positioned in slight extension and turned slightly to the right to expose the left side, but not so much as to bring the sternocleidomastoid muscle sharply across the carotid sheath. The optimal location for the carotid sheath dissection can be estimated by palpating the carotid artery and finding the point where the pulse burst becomes clear over the edge of the sternocleidomastoid. It is important to realize that the most desirable place for electrode placement is in the lower third of the neck, well below the carotid bifurcation, the area with which neurosurgeons have the greatest anatomical familiarity.

We initiate the procedure first with the incision for the generator pocket. There are different options of several different types of incisions, either on the chest wall itself for subcutaneous placement or more laterally, especially if the plan is to place the generator subpectorally. An incision parallel to the edge of the pectoralis muscle will often result in a widened scar, so we use one that follows the crease lines of the skin and therefore is almost perpendicular to this muscle approximately 5 cm below the level of the clavicle. This gives far better healing and a better cosmetic result.

Depending on the amount of subcutaneous adipose tissue, the surgeon opens the incision and then bluntly works to the edge of the pectoralis major. A small hollow is opened sharply and then, once opened, dissected bluntly to make a space large enough, either between the pectoralis major and minor or deep to the pectoralis minor, to easily hold the pulse generator. In smaller patients, this may be difficult and results in the generator being too laterally placed; therefore, subcutaneous placement is required instead. In this regard, the major advantage of thinner and smaller pulse generators, including the current Model 103, is that the incision does not have to be as long to admit and then secure the device. Once the plane is generated, an antibiotic- and/or a Betadine-soaked large sponge can be placed in the cavity as the surgeon proceeds to the cervical incision.

The neck incision, which may be as small as 2 to 2.5 cm, is made in the skin, again parallel to and often in a skin crease. The dissection is carried down to the platysma, where the planes are elevated to provide greater exposure. The platysma can be split parallel to the fibers, perpendicular to the skin

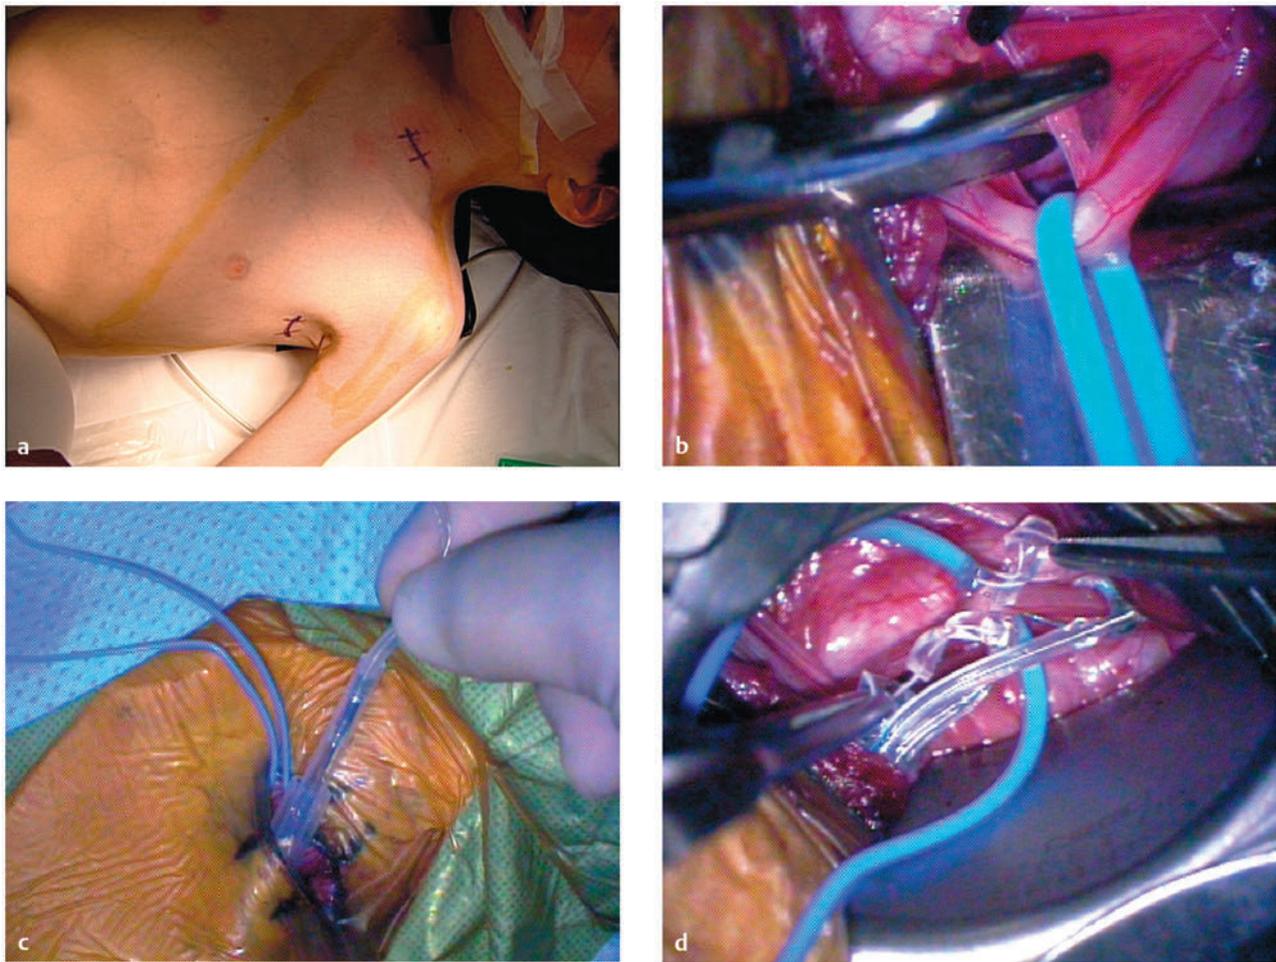

Fig. 74.3 Steps in the placement of a vagus nerve stimulator. (a) With the patient supine, incisions are marked in the direction of Langer lines in the skin, arranged to allow access to the carotid sheath in the lower neck, and tunneled up from the axillary pocket to the neck incision. This positioning allows an approach to the neck from both sides of the operating table and an approach to the axilla from the patient's left. (b) Short Cloward retractors provide visualization while the vagus nerve is dissected free from the carotid sheath. (c) The tunneling tool contains two concentric plastic tubes, the inner of which snugly fits the single-pin connector of the Model 303 or 304 leads. (d) The helices are placed around the nerve. (*continued*)

incision along the anterior border of the sternocleidomastoid, and more vertically to increase the exposure. Dissection can usually be followed down in a blunt way toward the palpable carotid pulse in an avascular plane, in a technique similar to what one would use for a carotid endarterectomy.

The omohyoid and other strap muscles are retracted inferiorly and medially as the sternocleidomastoid is retracted laterally with self-retaining retractors to provide the requisite exposure. It is possible to find the carotid sheath very efficiently and start to identify the translucent fascial plane that invests the jugular vein and internal carotid artery.

Usually, with gentle retraction and dissection in line with the vessels between the jugular and the carotid, the vagus nerve can be visualized, most often just posterior and lateral to the carotid. It is a large-diameter nerve and is usually more adherent to the jugular vein than to the carotid artery. Sharp dissection of the carotid sheath on both sides of the vagus nerve mobilizes it sufficiently so that a vessel loop can be passed underneath and around it. Early loop placement facilitates

visualization of the planes and mobilization without injury to the nerve. In general, approximately 2.5 to 3 cm of the nerve should be dissected free of the adherent sheath to provide enough length for the electrode leads. The topology of the investing sheath is such that two parallel incisions are made, one on either side of the nerve.

The choice of 2- or 3-mm helices for the electrodes depends on the caliber of the nerve. The packaging is opened once the nerve is visualized to decrease the time of exposure of the components. The electrodes are tunneled with the manufacturer-supplied tunneling device, which includes an inner and an outer tunneling tube, from the axillary incision medial and superior in the pocket toward the neck incision. A bend can be made in the device to make the necessary turn, or because of the very short distance involved, the tunneler can be used without bending the leading segment. Once tunneling has proceeded over the edge of the clavicle and into the superior surgical cavity deep to the platysma, the pointed tip of the probe is removed, and the electrode connectors are inserted into the

Fig. 74.3 (continued) (e) Silastic (Dow Corning, Midland, MI) anchors are sutured to the carotid sheath tissue to create the lower strain-relief loop in the cable. With a small incision, all three helices may not be seen in one view. Here, the anchor helix (with no electrical contact) is shown at the left, and the negative lead is shown in the cranial direction from it. The helix in the most cranial position, the positive lead, encircles the vagus nerve, unseen to the right. After the generator is secured with the torque wrench (f) and placed in its pocket (g), impedance testing with the handheld programmer is performed (h). Incisions are closed with subcuticular absorbable suture and epidermal adhesive.

inner tubing and pulled from the neck incision down into the pocket incision. We often place an antibiotic-soaked cover to reduce exposure while the leads are placed around the vagus nerve.

The following process of actually putting the helices onto the nerve is simplest to perform and teach in our hands. There are three coils—the negative and positive leads and the anchor or strain reliever. Typically, with very gentle retraction applied to the nerve upward with the vessel loop, and starting at either end and working vertically, each of the electrodes is grasped gently, one at a time for each pair of stringlike attachments in the helices, and stretched slightly to allow opening of the cleft between the helical turns. The superior turn is crossed over from medial to lateral and the inferior is crossed over from lateral to medial to ensure contact of the metal electrode portion of the helix to the nerve. This can be done with one movement of two pairs of forceps to resolve in a revolution and a half of helix around the nerve. The additional part of the helix can be teased into place with a variety of instruments, until the entire helix is entirely wound around the nerve. As a caution, if it seems to be very difficult to get the helix around the nerve, the

problem may be that the surgeon has forgotten that this is truly a right-handed helix system and has tried to put it on in the wrong orientation, which will very likely result in failure.

After the electrodes have been positioned on the nerve, it is necessary to make redundant loops so that movements of the neck do not dislodge the electrodes or put strain on the vagus nerve itself. A small space can be bluntly dissected with a right-angle dissector along the nerve in the carotid sheath going inferiorly and superiorly for these loops. Using the Silastic pledgets included with the electrodes, the doubled part of the cable is passed first inferiorly for a couple of centimeters and secured medially with, preferably and if possible, two tie-downs and 4-0 nonresorbable suture through the middle of the folded wings of the Silastic tie-downs. The loop is then passed superiorly and down parallel to the sternocleidomastoid muscle, where another two Silastic pledgets can be secured to the inner surface of the muscle so that the tie-downs are not easily palpable through the skin. The purpose of these relaxing loops is that movements of the neck, which can cause very dramatic changes in the distance between the sternocleidomastoid muscle and the carotid sheath, result in stretching and pulling on only the part of the cable

between the two tie-downs, and not on the part that is not directly sutured to or otherwise fixed to the nerve.

Vagus Nerve Stimulation: Initial Programming of the Generator Device

Our preference has been to have the devices turned on at the time they are being implanted. Although the risk for cardiac arrhythmias with the initiation of VNS is very low, we prefer to screen with continuous cardiac monitoring for untoward cardiac responses in the controlled environment of the operating room and a monitored bed immediately post operatively. Many practitioners nevertheless do follow the manufacturer's recommendation not to have the device activated at the time of the initial surgery. The pulse generator can be programmed before implantation while it is still in its package. Programming is performed with a handheld mobile device attached to a wand that communicates with the pulse generator via radio-frequency waves.

During the closure, the wand is draped in a sterile fashion, and the device is interrogated again and a lead test performed. The lead test now delivers a current in the range at 0.25 mA (compared with 1 mA in the older software versions), so the risk for cardiac or other autonomic complications during the lead test is less than in earlier models. As discussed below, a severe bradycardia that may need to be treated with vagolytic agents develops in approximately 1 in 600 patients (in the registry including all ages), but these data were reflective of the higher lead test currents.

Vagus Nerve Stimulation: Insertion of the Pulse Generator

The leads themselves are attached and anchored with a single set screw for the single two-contact pin for the Model 103 generator or with two separate electrodes that have separate pins for the Model 104 (which is a modification of the Model 103 designed to accept the older electrode pins). The device is secured in the subcutaneous pocket with nonresorbable suture. When a subcutaneous placement is made for a patient with a thicker adipose layer, the attachment is to the pectoralis major; otherwise, muscle deep to the pocket is used. The muscle is then closed over the pocket with interrupted resorbable sutures. The neck wound is also closed in a multilayered fashion. Care is taken to reapproximate the platysma with braided resorbable suture to ensure a good cosmetic result. The skin is typically closed with resorbable monofilament (4-0 or 5-0) and a subcuticular stitch, with a tissue adhesive placed over the suture line to protect the incisions. Sterile bandages can be placed over the wounds for further protection.

Vagus Nerve Stimulation: Postoperative Care

Patients are advised to keep the incisions clean and dry for several days to a week, and then the outer dressings can be removed. Frequently, these procedures are performed on an outpatient basis, and only the initial perioperative antibiotic dose is given. Interscapular placement of a VNS pulse generator can be used for very young children to prevent wound tampering, but we have found satisfactory results with the more standard subpectoral placement.

Postoperatively, patients are scheduled to visit their physician regularly every few days to weeks. The device is programmed to ramp up the current and to optimize the settings, which most often settle at around 1 mA. In most practices, this is done by a neurologist or epileptologist, although some pediatricians can be instructed through the primary neurologist if the child lives in a rural community or far away from the epilepsy center. The interval between stimulation sessions, the so-called off-time, can be decreased if the patient seems to need more stimulation to achieve a therapeutic effect.

For reasons that are not clear, sometimes even at the same dose of current, the effectiveness of stimulation may increase with time. In some ways, this is the reverse of the phenomenon of kindling, in which a low level of stimulation may eventually cause a seizure; here, long-term low-level repetitive stimulation seems to inhibit seizures. The actual underlying pathophysiology of this is not understood.

74.3 Future Directions

As with most fields in neurosurgery, surgical treatment options for medically refractory epilepsy are trending toward less destructive, more minimally invasive techniques. There has been a paradigm shift of moving away from simply anatomical removal or disconnection procedures to more dynamic systems of neurostimulation. Neurostimulation has several advantages over ablative-type surgeries, including reversibility, a lower risk for permanent neurologic deficits, and the ability to impact multiple foci with a single target. Furthermore, neurostimulation offers the ability to modulate circuits postoperatively, to individualize treatment and to maximize therapeutic benefit. Disadvantages are the need for implantation, potential failure of the technology at the lead or generator level, and the lack of a "cure" for the epilepsy. As a technique, neurostimulation remains in its infancy and is far from realizing its full potential. Most of the current applications involve open-loop systems that provide continuous, round-the-clock stimulation. However, a large research effort is aimed at developing efficacious closed-loop systems to allow the continuous monitoring of brain activity and the delivery of electrical stimulation only when peri-ictal electrical activity is detected. Although closed loop systems are promising, more sophisticated technology is needed for more sensitive and specific detection of abnormal activity.

As the technology continues to advance, the number of potential neural targets for neurostimulation continues to expand. Beyond the multitude of central nervous system targets that have been investigated (as described above), new peripheral targets have emerged. Stimulation of both the trigeminal nerve and glossopharyngeal nerve (branch known as the Hering nerve) has demonstrated potential benefit for the treatment of epilepsy.¹⁵⁹⁻¹⁶² Further bench-top and clinical experimentation is needed to validate its utility.

Farther along the minimally invasive spectrum, repetitive transcranial magnetic stimulation (rTMS) has been introduced as a potential treatment option for epilepsy.¹⁶³ rTMS is a noninvasive technique that uses an extracranial electromagnetic field to induce cortical neuronal currents. The impact of various frequencies and pulse trains on neural excitability has been studied extensively. There is now evidence from several clinical trials that rTMS may be effective in the treatment of seizures.¹⁶⁴⁻¹⁶⁷

Because the electromagnetic force is strongest at the cortical surface, rTMS may be most effective in the treatment of cortical epileptogenic foci. Currently, investigators are working to optimize stimulation parameters and to characterize the efficacy of rTMS for various seizure disorders.

A separate frontier focuses on cellular and molecular strategies for seizure reduction in medically refractory epilepsy. Many avenues are currently being explored, including the application of stem cell–based therapies, gene therapy (e.g., galanin, neuropeptide Y, neurotrophic factors, adenosine-based therapies), focal drug delivery (e.g., delivery directly to a seizure focus, cerebrospinal fluid–disseminated delivery), and optogenetics.^{162,168} Although most of these strategies remain at the basic science level of investigation, they all demonstrate clinical promise, and collaboration with neurosurgeons will be required for implantation and other surgically based modes of delivery.

Pearls

- Any child with refractory epilepsy who is not a good candidate for a resective procedure (i.e., nonlocalizable partial complex epilepsy, generalized seizures, multifocal epilepsy) should be considered for nonresective approaches, such as disconnection procedures or neurostimulation. Discussion should begin with the families early so that they understand that failure of medicines will lead to a recommendation for surgical intervention.
- Corpus callosotomy is a disconnection procedure that is highly effective for drop attacks and atonic seizures.
- One-stage, complete corpus callosotomy may be indicated for patients with severe neurologic deficits or neurocognitive/speech impairment.
- Anterior two-thirds callosotomy may be appropriate for patients who can read or are expected to be able to read in the future.
- Callosotomy can be performed through a small craniotomy just in front of the bregma, but a slightly larger craniotomy enables the surgeon to avoid bridging veins by changing the angle of the approach.
- Finding the exact midline within the corpus callosum allows dissection of the raphe between the ventricles and in most cases permits callosotomy without entry into the ventricular system.
- Neurostimulation can be divided into closed- and open-loop systems.
- Open-loop systems, such as DBS and VNS, provide continuous neurostimulation.
- Closed-loop systems, such as RNS, monitor for ictal activity and provide neurostimulation only when prompted.
- Despite FDA labeling for use in patients with refractory partial epilepsy who are 12 years old or older, in our experience, the results for children younger than age 12 are as good if not better than those for older patients. Because of the low risk of surgical implantation and the high risk of inadequately treated intractable seizures, a recommendation for surgical evaluation and ultimately VNS as indicated should be introduced to the family early in the discussion of options.
- Placement of the vagus nerve generator deep to the pectoralis may be appropriate in very young or very thin children.

75 Hemispherectomy

Alexandra D. Beier and James T. Rutka

Intractable epilepsy is a devastating disease, not only for the patient and family but also for the primary healthcare provider, neurologist, and treating neurosurgeon. Neurosurgical options include invasive monitoring with tailored resection, multilobar removal, multiple subpial transections, and hemispherectomy involving a variety of techniques. This chapter provides an overview of hemispherectomy—its history, the neurosurgical options and indications, techniques, and outcome.

75.1 History

75.1.1 Anatomical Hemispherectomy

The removal of one cerebral hemisphere, or hemispherectomy, was initially described for the control and potential cure of malignant glioma. In 1928, Dandy described a series of five patients in whom an anatomical hemispherectomy was performed by ligating the main cerebral arteries, dissecting the hemisphere off the falx medially, and incising along the corpus callosum and internal capsule, thus delivering the hemisphere.¹ Gardner also published his results on hemispherectomy for gliomas in 1933.² Although the mortality of the procedure was high, on the order of 40 to 66%, both surgeons felt that the risk could be countered by an extended life span.^{1,2} Sadly, improved survival was never fully realized, and patients lived out the remainder of their lives with the added functional impairments created by the surgery.

McKenzie was the first to perform a hemispherectomy for epilepsy in 1938. The patient was a woman who had intractable epilepsy associated with infantile hemiplegia. Krynauw presented a series of 12 patients with infantile hemiplegia and popularized the technique in 1950.^{3–5} Krynauw reported that the main indication for surgery was not preoperative hemiplegia; rather, it was persistence of seizures and resultant cognitive impairment. In his experience, focal surgery might occasionally stop the seizures, but there would be no improvement in mental functioning or physical disability. Krynauw believed that any residual diseased hemisphere would continue to emit electrical discharges that would eventually spread to and involve the anatomically normal hemisphere, thereby potentially continuing to affect intellect as well as inducing secondary foci of epileptogenesis. Thus, he advocated removal of the entire hemisphere.⁵

The initial enthusiasm for hemispherectomy waned when in 1966 Oppenheimer and Griffith reported 3 delayed deaths in a series of 17 patients with anatomical hemispherectomy. Autopsies revealed obstructive hydrocephalus with superficial hemosiderosis, which was thought to be due to repeated episodes of bleeding within the cranial cavity. They suggested that to decrease the risk for hemosiderosis, the abnormal hemisphere should be functionally disconnected and left in place with an intact ventricular lining or that, as an alternative, the ipsilateral ventricular cavity should be occluded from contact with the other side.⁶

Modifications and variations of the neurosurgical technique ensued. Wilson initially discussed decreasing the volume of the

hemispheric cavity in 1968, and Adams further illustrated this concept in 1983 with his “Oxford” modification, which consisted of two steps: First, the ipsilateral foramen of Monro was plugged with muscle to prevent the drainage of blood products into the ventricles; second, the dura was stripped off the bone and tacked to the falx, the tentorium, and the floor of anterior and middle cranial fossae to reduce the volume of the cavity and thus expand the extradural space.^{7–9} The Peacock modification included drainage of the hemispherectomy cavity with a subdural peritoneal shunt.¹⁰ Anatomical hemispherectomy achieves good seizure control, with 80 to 90% of patients obtaining an Engel Class I or II outcome.^{11,12}

75.1.2 Functional Hemispherectomy

In 1974, Rasmussen developed the functional hemispherectomy. This was after subtotal hemispherectomies had been performed in a series of 48 patients from 1937 to 1971 to decrease the risk for hemosiderosis yet resulted in worsened seizure control.⁹ Rasmussen’s procedure involved a subtotal anatomical hemispherectomy with disconnection of the remaining cerebrum from the contralateral hemisphere to obtain the same overall result as that of an anatomical hemispherectomy.^{9,13} The remaining tissue protected the brain from hemosiderosis, but the result was similar to that of an anatomical hemispherectomy, with a seizure-free rate of 75%.³ As well, the incidence of postoperative hydrocephalus was less because a greater amount of the subarachnoid space was left intact.¹³

75.1.3 Hemispherotomy

Other modifications to Rasmussen’s first description of functional hemispherotomy have been made. The techniques differ from one another in regard to the volume of resected brain; the route of access to the lateral ventricle; whether insular resection, hippocampal resection, or disconnection is performed; and whether there is vascular preservation or sacrifice in the peri-insular area.³ The term *hemispherotomy* describes a small amount of cerebral resection with extensive disconnection. In the 1990s, Delalande and colleagues described a vertical approach, while Ville-mure et al and Schramm et al described a lateral approach.^{3,8,14,15} Seizure freedom rates ranged from 74 to 85%.^{3,16} Details are further elucidated in the section on surgical technique.

75.1.4 Hemidecortication

In the initial description, hemidecortication or hemicortication was similar to hemispherectomy; however, instead of removal of the hemisphere en bloc, a small amount of white matter was left over the ventricular system.¹⁷ Winston in 1992 and Hoffman in 1993 further detailed the procedure as “degloving” of the cerebrum because the cortical gray matter was resected down to the white matter, with preservation of the underlying white matter and ventricular system.^{3,12,18} This prevented bloody contamination of the ventricular system. The main problem with this procedure is blood loss and the technical

difficulty of performing complete cortical resections on the medial and basal sides of the lobes.^{3,19,20} However, hemidecortication has resulted in long-term seizure freedom in 50 to 80% of patients, depending on their underlying disorder. If the anatomy of a hemispherectomy is unfavorable to ventricular approaches, then hemidecortication should be considered for patients with severe seizure disorders.²⁰

75.2 Neurosurgical Procedure

75.2.1 Indications for Surgery

To identify a surgical candidate, the concept of medically intractable seizures is raised. Interestingly, what defines medically intractable seizures is not always agreed upon in the literature. Intractability is defined as failure of three first-line antiepileptic medications in infants, whereas in adults, a failure of two antiepileptic medications over 2 years has been used to define intractability. However, in infants with frequent seizures, the duration of drug trials may be brief, and there is a risk with waiting because irreversible cognitive deficits may develop. As well, an early age at seizure onset, a remote symptomatic etiology, infantile spasms, status epilepticus, a poor response to short-term antiepileptic therapy, and failure of an initial antiepileptic drug trial can all predict intractability.²¹ Other indications for surgery include a seizure disorder limited to one hemisphere for which multifocal resections would seem inadequate.²² Preoperative hemiparesis or hemiplegia is preferable because it lessens the postoperative deficit; however, it is not mandatory because there are certain progressive conditions with a well-known natural history that result in the worsening of motor and cognitive function. Catastrophic infantile epilepsy syndromes causing multiple daily seizures put the brain at developmental risk. Therefore, these children may be considered candidates for early surgery because hemispherectomy may avert a decline in cognitive function.³ Diffuse hemispheric disorders for which hemispherectomy has been employed include Sturge-Weber syndrome, cortical dysplasia, hemimegalencephaly, Rasmussen syndrome, porencephalic cyst, and hemiconvulsion-hemiplegia-epilepsy syndrome.^{3,22} (► Fig. 75.1 and ► Fig. 75.2)

Sturge-Weber Syndrome

Patients with Sturge-Weber syndrome typically have hypertrophic pial vessels, and the venous sinuses and veins are frequently absent. The result is a strong retrograde venous flow into the ventricles, and the aberrant cerebral vasculature creates a hypoxic environment as blood is shunted away from the parenchyma. This leads to cellular damage and secondary seizures. Patients typically present with seizures in the first year of life, which begin as simple or complex partial seizures that can secondarily generalize. In patients with diffuse Sturge-Weber syndrome, hemispherectomy is recommended early because their condition will progress to intractable epilepsy, hemiplegia, and cognitive impairment.^{3,22}

Cortical Dysplasia

Intractable epilepsy is seen in patients with unilateral multilobar or extensive cortical dysplasia. Cortical dysplasia has been

described as the most common underlying surgical pathology in children with intractable epilepsy. It is characterized by a disturbance of the normal cortical lamination, with resulting abnormal cells and neuronal circuitry that lead to increased epileptogenicity. The epilepsy type depends on the amount and location of cortical dysplasia but is usually chronic and consists of partial or generalized seizures.^{3,23}

Hemimegalencephaly

Hemimegalencephaly is a hemispheric neuronal migrational disorder. An enlarged hemisphere with lamination of only three to four layers, heterotopias, flat gyri, giant neurons, shallow sulci, poor gray-white matter differentiation, and an abnormal ventricular system characterize this disorder. Partial seizures with generalization lead to intractable epilepsy. Epileptic encephalopathy and developmental delay are the outcomes for these patients if they are not aggressively treated.^{3,22}

Rasmussen Syndrome

Rasmussen syndrome is an acquired progressive disease described as chronic encephalitis with spreading cortical inflammation that results in seizures, typically *epilepsia partialis continua*. The patients experience intellectual deterioration and progressive hemiparesis.^{3,22}

Porencephalic Cyst

Porencephalic cysts result from perinatal insults and traumatic brain injuries. Etiologies include large infarcts, intracranial hemorrhage, and coagulopathies. The epilepsy is typically medically intractable, and hemiplegia is commonly found.³

Hemiconvulsion-Hemiplegia-Epilepsy Syndrome

Hemiconvulsion-hemiplegia-epilepsy syndrome has three phases. It initially presents with unilateral, prolonged clonic seizures that affect the face, arm, and leg. This is followed by hemiplegia and partial epileptic seizures. Chronic epilepsy evolves within 1 to 2 years. The etiology of this disease is unknown.³

75.2.2 Preoperative Planning

At The Hospital for Sick Children, all patients are evaluated by an experienced pediatric epileptologist, an epilepsy surgeon, and a neuropsychologist if age permits, and they are discussed at a multidisciplinary epilepsy conference. Ancillary studies include interictal and ictal scalp video electroencephalography (EEG), magnetic resonance (MR) imaging, and frequently positron emission tomography (PET) and functional MR imaging (fMRI). Wada testing is not always feasible in children and also carries a risk for ischemia of the unaffected hemisphere.³ Patients at The Hospital for Sick Children routinely undergo magnetoencephalography (MEG). Torres et al recently reported on the contribution of MEG to patient selection for hemispherectomy. With a small cohort, they found that MEG correlated with video EEG in most patients; however, a lack of MEG spikes in

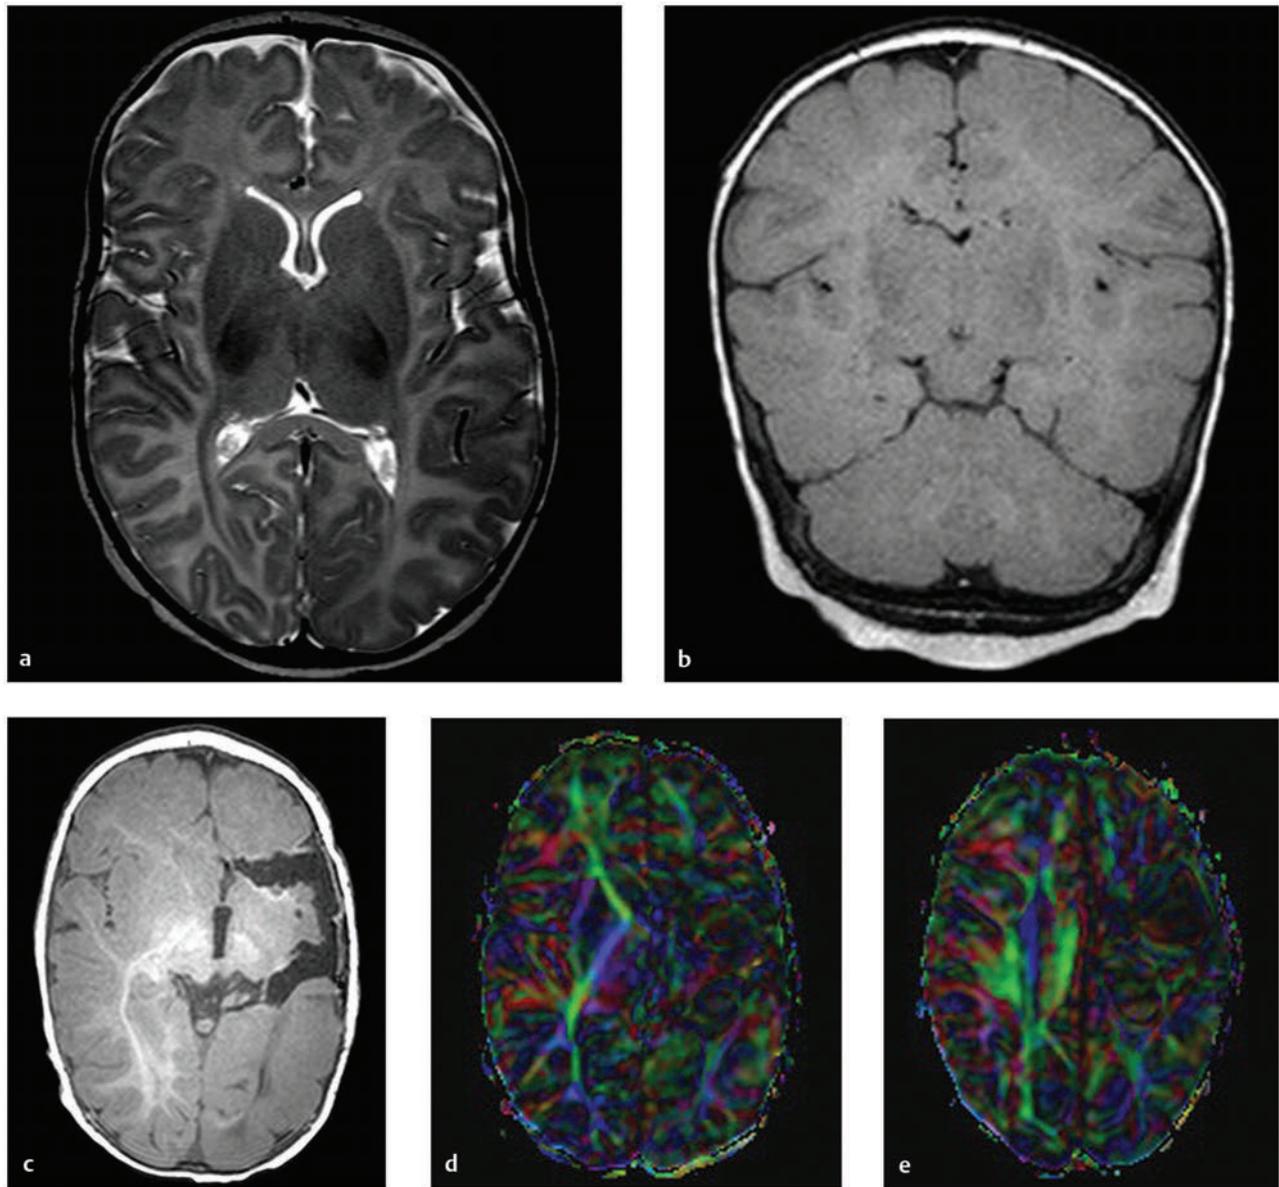

Fig. 75.1 Hemimegalencephaly. (a) Axial T2-weighted image showing thickening in the left occipital, temporal, and parietal lobes. (b) Coronal FLAIR (fluid-attenuated inversion recovery) image revealing enlargement of the left occipital and temporal lobes. (c) T1-weighted image 6 months after hemispherotomy. (d,e) Diffusion tensor imaging elucidating the functional disconnection of the left hemisphere.

the contralateral hemisphere was not a predictive factor for seizure-free outcome.²⁴ A larger cohort will likely allow further delineation of the information obtained from MEG.³

EEG will help determine if the epileptiform discharges are limited to one hemisphere. As well, predictors of good outcome are the following: ipsilateral suppression of electrical activity associated with multifocal epileptiform abnormalities confined to the damaged hemisphere; bilateral synchronous discharges spreading from the abnormal hemisphere without contralateral slowing; and the absence of generalized discharges, bilateral independent spiking, and abnormal background activity in the unaffected hemisphere. Although they do not exclude a patient from hemispherectomy, the following abnormalities in the “unaffected” hemisphere may denote an

unfavorable outcome: sporadic epileptiform discharges, abnormal secondary or independent EEG findings, and nonepileptiform abnormalities. This is especially true if independent interictal sharp wave activity is observed in the unaffected hemisphere.^{3,8}

The anatomical details gleaned from preoperative imaging to assess the feasibility of hemispherectomy include the following: ventricular size, shape and depth of sylvian fissure, location of the circular sulcus, displacement of the normal landmarks, thickness of the corpus callosum, surface anatomy, presence of parenchymal atrophy, and abnormal vasculature. It has been noted that the presence of atrophy in the ipsilateral cerebral peduncle and medulla helps to predict a lower risk for postoperative worsening.³

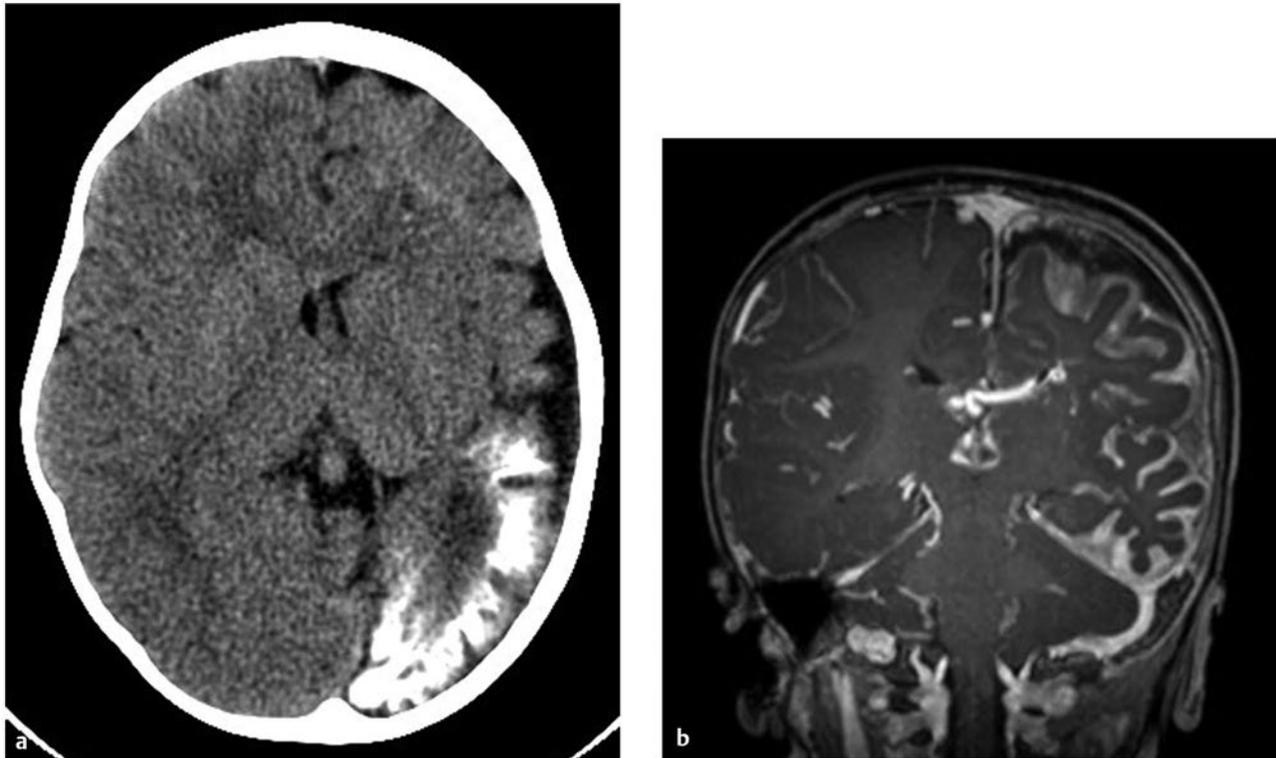

Fig. 75.2 Illustrative imaging studies depicting the neuropathology of cases for which hemispherotomy is indicated. (a,b) Axial computed tomographic scan and coronal T1-weighted magnetic resonance (MR) image with contrast of Sturge-Weber syndrome. (*continued*)

On metabolic studies, confinement of the hypometabolic and epileptogenic areas to the damaged hemisphere has been shown to be a good predictor of outcome. By the same token, if the hypometabolic areas spread into the normal hemisphere, this is an indicator of more extensive and perhaps bilateral involvement.³

75.2.3 Timing of Surgery

The ideal time for surgical intervention is debated. The goal of surgery is to protect the brain from the harmful effects of seizures and antiepileptic drugs. These effects on the immature brain, as well as the plasticity of the younger brain, argue for earlier surgery. After the sixth to eighth year, the ability of the dominant hemisphere to acquire language declines, which further supports earlier surgery. Additionally, the shorter the time between seizure onset and surgery, the higher the success rate, and earlier seizure control optimizes psychosocial development.^{3,22}

75.2.4 Techniques of Hemispherectomy

As described before, there has been an evolution from anatomical hemispherectomy to functional hemispherectomy to hemispherotomy. The difference in terminology reflects the amount of cerebral cortex resected. The anatomical hemispherectomy resects the largest amount of cortex, whereas the functional hemispherectomy combines a partial resection with a partial disconnection. Finally, the hemispherotomy resects a small amount of cortex and maximizes disconnection.⁸

Anatomical Hemispherectomy

For a description of the anatomical hemispherectomy, the reader is referred to the article of Di Rocco et al.¹¹ A question mark-type or a T-shaped skin incision can be used. An osteoplastic craniotomy can be fashioned, or a myocutaneous skin flap can be used with a standard craniotomy. The bone flap needs to be placed close to the sagittal sinus. The hemispherectomy is initiated by exposing the distal internal cerebral artery. The middle cerebral and anterior cerebral arteries are clipped and divided. Attention is then paid to the interhemispheric cleft. The medial surface of the hemisphere is retracted, and the bridging cortical veins are divided to reach the corpus callosum. The ipsilateral pericallosal artery is divided, and the callosotomy is performed from the genu to the splenium. Once the lateral ventricle is opened, the foramen of Monro is plugged.

A transventricular endypymal incision lateral and anterior to the basal ganglia is made to detach the frontal lobe from the basal ganglia. The frontal lobectomy is completed by extending the endypymal incision up to the sylvian fissure and then continuing the incision from the fissure to the midline. Next, the parietal, occipital, and temporal lobes are disconnected. The posterior cerebral artery is divided at the level of its P3 segment. The temporal stem is divided by extending the previously created endypymal incision posteriorly to the trigone area and temporal horn. After coagulation of the bridging veins, the parieto-occipital lobe is freed with the temporal lobe and can be removed en bloc or in piecemeal fashion. An amygdalohippocampectomy is performed with subpial dissection or aspiration. The

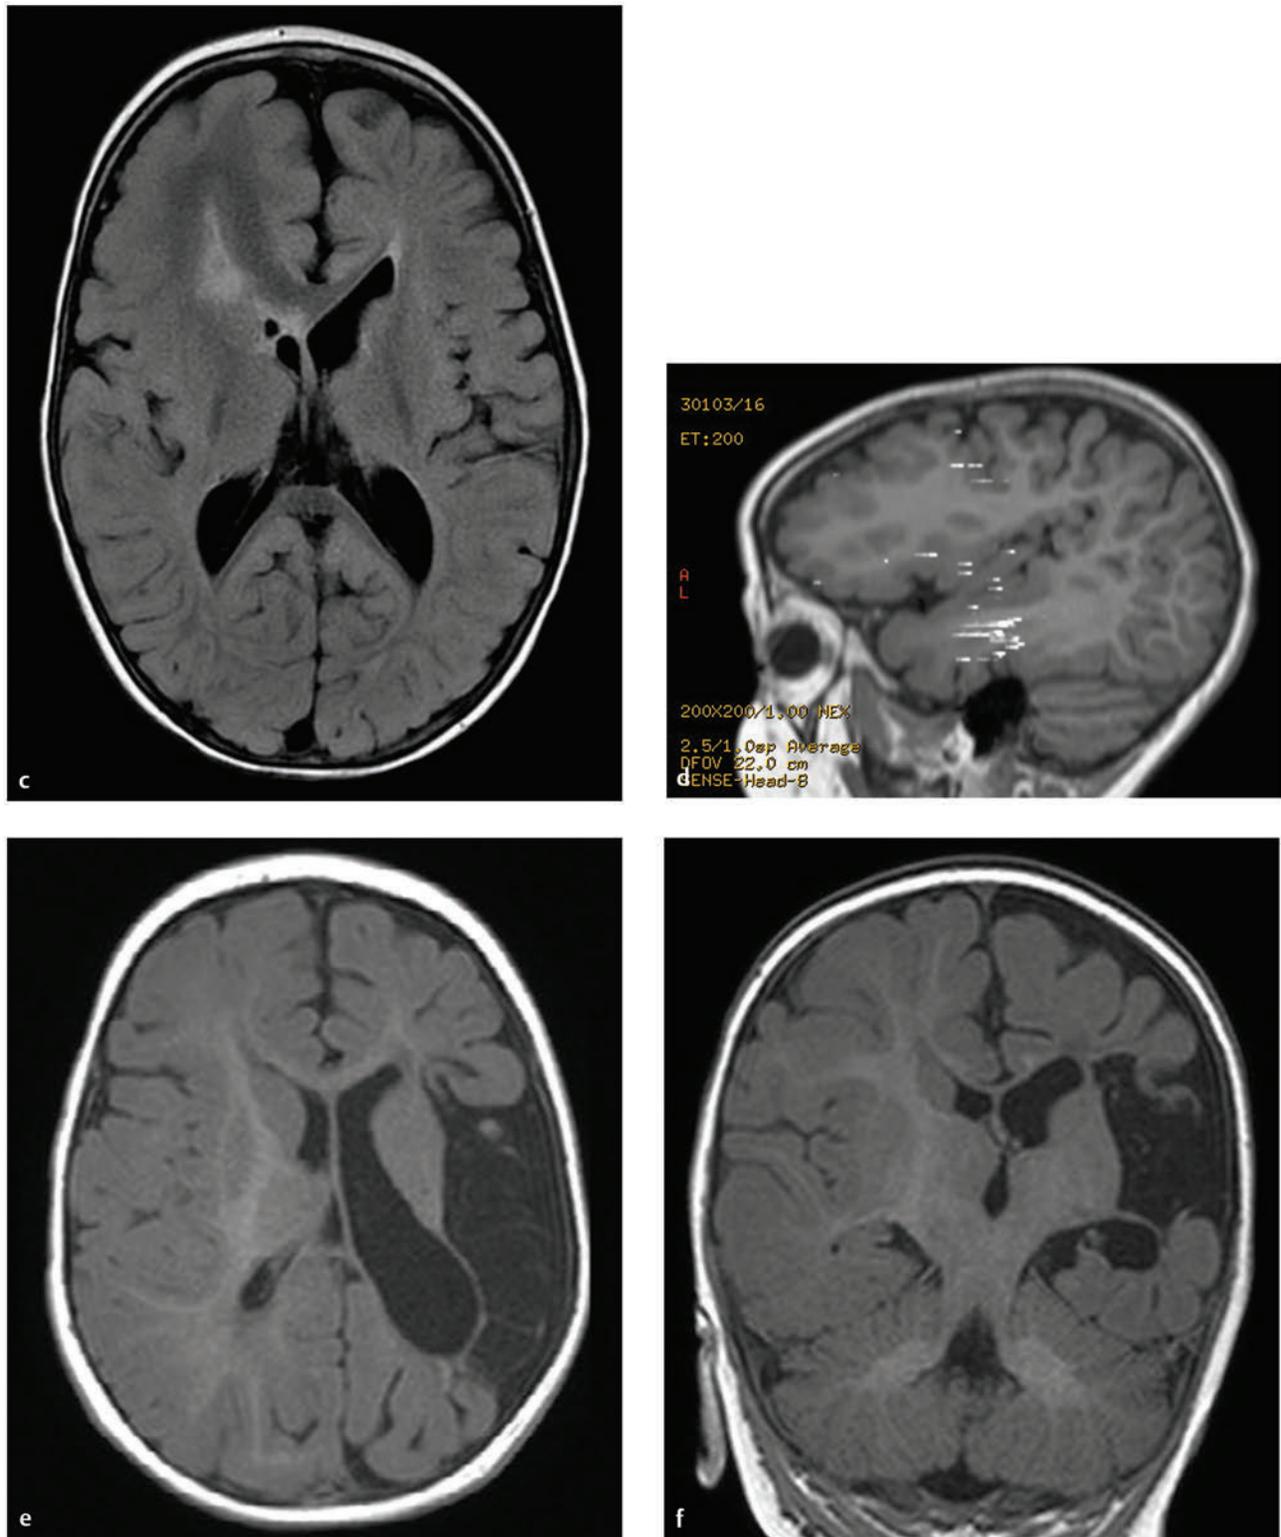

Fig. 75.2 (continued) (c,d) Axial FLAIR (fluid-attenuated inversion recovery) MR image and magnetoencephalogram of hemimegalencephaly. (e, f) Axial and coronal T1-weighted MR images of perinatal middle cerebral artery infarct.

basal ganglia are left in situ unless they are felt to be involved in the cortical malformation, with a risk for recurrent seizures.¹¹

As described previously, the Oxford modification consists of plugging the foramen of Monro and tacking the dura to the tentorium, falx, and floor of the middle cranial fossa to decrease the subdural space.⁷ As well, the Peacock addition includes routine subdural drainage with placement of a shunt in the early postoperative period.¹⁰

Functional Hemispherectomy

Rasmussen's functional hemispherectomy was the first attempt at subtotal removal with disconnection. This consists of temporal lobectomy, resection of the central region, and disconnection of the residual frontal and parieto-occipital lobes from the remaining brain, with preservation of as many arteries and veins as possible. The insular cortex is preserved unless corticography has indicated spiking, in which case a subpial resection is performed.⁹ The goal is to provide functional disconnection while preserving a large part of the brain to avoid the complications of a large surgical cavity.³

Hemispherotomy

The term *hemispherotomy* was introduced by Delalande et al in 1992 to describe minimal brain resection with maximal disconnection for intractable epilepsy.¹⁵ These procedures can be performed with a vertical or a lateral approach. Delalande and colleagues described a vertical approach. A linear transverse skin incision is made to allow a small parasagittal frontoparietal craniotomy that is based two-thirds posterior to the coronal suture and one-third anterior. A corticectomy is made to enter the lateral ventricle. A callosotomy is performed, and the posterior hippocampal disconnection is made by transecting the posterior column of the fornix at the level of the ventricular trigone. The corona radiata is transected to reach the temporal horn. An incision from the gyrus rectus to the anterior temporal horn creates the anterior disconnection.^{14,15,25} In 2001, Danielpour et al modified this technique by starting the vertical approach interhemispherically.^{3,26}

The lateral approach was described similarly by Villemure and Mascott and by Schramm et al in 1995.^{16,27} Schramm et al describe it as starting with a hippocampectomy or a hippocampectomy with an anterior temporal lobectomy. After this, deafferentation of the white matter of the temporal, occipital, parietal, and frontal lobes is performed. This can be done with a transcortical transventricular approach along the outline of the lateral ventricle. The callosotomy is performed transventricularly. A small portion of the supra-insular cortex remains, as well as the insular cortex. However, as a modification, the insular cortex can be resected. Another modification allows the entire transventricular deafferentation to be performed through a sylvian keyhole.

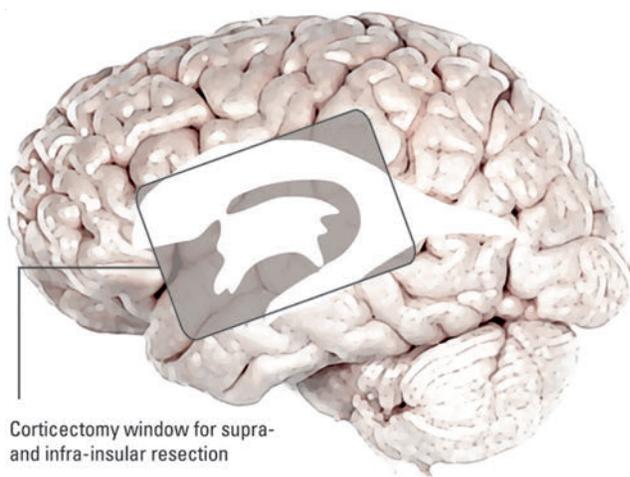

Villemure and Mascott described the technique of lateral peri-insular hemispherotomy in 1995. The authors stated it could be viewed as a "radical hemispheric tractotomy" resulting in a completely disconnected hemisphere.²⁷ The craniotomy is based over the circular sulcus and the ventricular system. The peri-insular hemispherotomy has three major surgical stages: supra-insular window, infra-insular window, and insula. In the

supra-insular window, the frontoparietal opercular cortex is resected, followed by the transection of the corona radiata and the transventricular callosotomy. The posterior hippocampectomy is completed, and the frontobasal disconnection completes the supra-insular window. The infra-insular window starts with the resection of the temporal opercular cortex, followed by the transection of the temporal stem. Next, the amygdala is resected, and the anterior hippocampectomy is completed. Finally, the insular stage consists of subpial aspiration of the insula or disconnection by incising at the level of the claustrum or extreme capsule.²⁸

There have been several modifications to the peri-insular hemispherotomy. The universal steps are disruption of the internal capsule and corona radiata, resection of the medial temporal structures, transventricular callosotomy, and disruption of the horizontal fibers.²⁹ Shimizu and Maehara introduced the transopercular hemispherotomy.³⁴ The upper half of the insula is exposed through a transsylvian approach. The arteries of the insula are coagulated and divided. Next, the frontoparietal operculum and the upper half of the insula are resected en bloc. This creates a large cavity for which the disconnection and medial temporal lobe structures occurs.^{25,29} Comair used the transsylvian approach to perform the peri-insular disconnection. This involved a vertical incision from the insula to the temporal horn, thus allowing removal of the mesial temporal lobe structures. As well, a cortical incision is made to perform the callosotomy.²⁹ Kanev et al used ultrasound to perform hemispheric disconnection without violating the ventricular cavity.³⁰ In 2004, Cook et al described the modified lateral hemispherotomy. The goal was to reduce the blood loss seen with anatomical hemispherectomy and to decrease the reoperation rate seen with the Rasmussen functional hemispherectomy. It was also postulated that it would be key for children with small or malformed ventricles. This procedure creates a working space around the ventricles by removing most of the thalamus, basal ganglia, caudate nucleus, and other associated deep hemispheric structures. These deep structures were felt to be the cause of recurrent seizures that hinder the effectiveness of functional hemispherotomy.³¹ Other recommendations have been made to limit the size of the insular window to maintain as many middle cerebral artery branches as possible.^{29,32}

At The Hospital for Sick Children, we have been using a modified peri-insular hemispherotomy approach. The patient is secured in a Sugita head holder (Mizuho, Tokyo, Japan) or a horseshoe head rest if very young. Neuronavigation is used to assist in marking the skin incision as well as localizing the ventricle. A question mark-type incision is based over the insula. A frontoparietotemporal craniotomy based on the insula is created (► Fig. 75.3). The dura is opened in a curvilinear fashion with spokes radiating superiorly, inferiorly, and posteriorly. The supra-insular window is created by resecting the frontoparietal opercular cortex down to the insular pial bank. Next, the infra-insular window is fashioned similarly to resect the temporal opercular cortex. Care is taken to preserve as many branches of the middle cerebral artery as possible to avoid remote infarcts or ischemic changes (► Fig. 75.4).

The temporal lobe is then addressed. First, the lateral neocortex is resected and sent en bloc. Next the temporal horn is entered, and a cotton square is placed in the ventricle to mark its location. The anterior temporal tip can be removed at this

Corticectomy window for supra- and infra-insular resection

Fig. 75.3 Artist's rendering of the outline of a craniotomy for exposure of the supra- and infra-insular windows.

point. Performing an anterolateral temporal lobectomy will ensure sufficient space intracranially in the event of any post-operative cerebral swelling. The hippocampus is disconnected anteriorly, mesially, and posteriorly and removed en bloc. The amygdala is also resected as part of the procedure. If a decision is made not to remove the temporal lobe, including the mesial structures, it is important to open along the length of the temporal horn and then incise the fimbria fornix at the level of the splenium of the corpus callosum so as to functionally disconnect the temporal lobe.

The corona radiata is transected by opening the temporal horn posteriorly and continuing around to the frontal horn of the lateral ventricle. To aid in the directionality of this maneuver, one can follow the course of the choroid plexus, and as the ependyma is incised, care must be taken with many of the small ependymal veins, which must be coagulated and cut sharply to control hemostasis.

The callosotomy is performed from within the exposed lateral ventricle. One of the most reliable landmarks for finding the pericallosal vessels is just posterior to the foramen of Monro and superior to the fornix just before it courses inferiorly. Careful study of the preoperative MR images and the use of neuronavigation can sometimes assist in finding the pericallosal vessels in the subarachnoid space above the corpus callosum. Once the pericallosal arteries are found, the callosotomy can be carried out anteriorly by incising the callosum along the line of the arteries (► Fig. 75.5). As the callosotomy is continued posteriorly, the pericallosal arteries often taper, so the falx can then be followed down to the tentorium. By continuing this cut along the free edge of the tentorium to the posterior hippocampal cut, the posterior hippocampal disconnection is created, and the occipital lobe is disconnected.

The frontal disconnection is created by starting at the sphenoid wing and transecting the frontal lobe in a subpial fashion to the medial interhemispheric pia, staying anterior to the basal ganglia and ventricle. This is then connected to the rostrum callosotomy by following the incision to the pericallosal arteries.

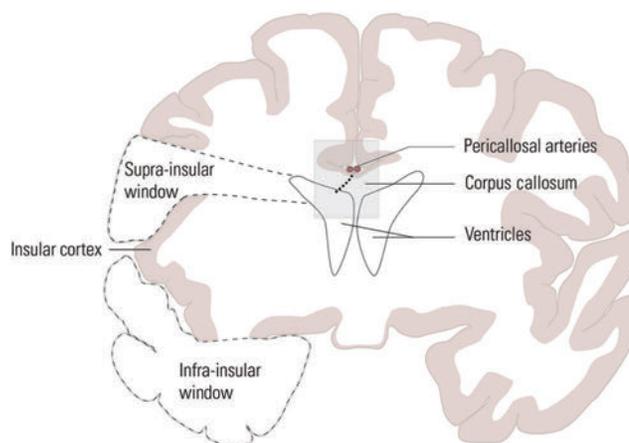

Fig. 75.4 Artist's rendering of a coronal view of the supra- and infra-insular windows and the incisions required to perform a corpus callosotomy (dotted lines).

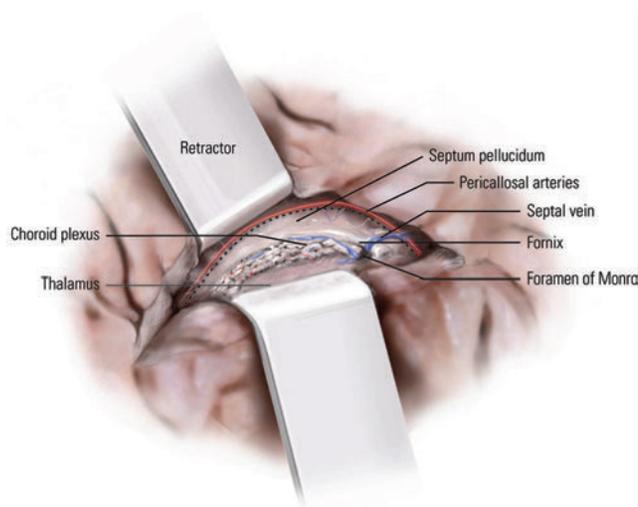

Fig. 75.5 Artist's rendering of the lateral hemisphere with focus within the lateral ventricle identifies the key landmarks for initiating a callosotomy, including the foramen of Monro, fornix, septal vein, and septum pellucidum.

Finally, the insular resection proceeds with subpial resection of the insular cortex. Again, the goal here is to preserve the many penetrating arteries that perfuse the deep gray matter structures and to remove only the cortex, which is about 3 mm in thickness.

75.3 Outcome

75.3.1 Seizure Control

Anatomical hemispherectomy can result in an 85 to 95% rate of good seizure control, defined as seizure freedom or a marked reduction in seizures.¹² Our results describing outcomes of peri-insular hemispherotomy have been previously published,

with 85 to 92% of patients having Engel class I or II outcomes.^{19, 24} These results are similar to those reported in other studies with a range of seizure control rates of 86 to 100%.^{15,19,28,33} As well, we have found better outcomes with Sturge-Weber syndrome, Rasmussen encephalitis, and focal infarct pathology, again supported in the literature.^{15,19,34}

75.3.2 Motor Outcome

Devlin et al described the clinical outcomes after hemispherectomy in 33 patients. They reported that preoperative hemiplegia remained unchanged in 67%, improved in 15%, and worsened in 18%.³⁵ Kwan et al, in a comparison of hemidecortication and peri-insular hemispherotomy, found that preoperative hemiparesis was present in 20 of 21 patients and in 16 of 20 patients, respectively. Although all had postoperative hemiparesis, 16 and 18 patients remained ambulatory.¹⁹ In the series by Kestle et al, there was no decrease in ambulatory status.³³

75.3.3 Neurocognitive and Psychological Outcome

Hemispherectomy appears to halt the progressive cognitive deterioration that is seen with catastrophic epilepsy syndromes. Devlin et al reported that the majority of patients had no further cognitive decline (23 of 33) and that 4 showed improved cognition. As well, of the 33 patients described by Devlin et al, 12 had preoperative behavioral problems. Of these, 11 significantly improved postoperatively, with 5 families reporting the resolution of behavioral symptoms. The remaining patient's behavior was unchanged.³⁵

75.3.4 Complications

Operative mortality with anatomical hemispherectomy has been reported at 1 to 7%, with the lower rate favored recently. Complications, such as cerebrospinal fluid leak, wound infection, and postoperative hematomas, parallel those in other neurosurgical procedures. However, the other common complications of blood loss and resulting anemia were the main cause of surgical mortality. Other complications included infarcts from the inadvertent contralateral clipping of vessels, brainstem distortion or edema secondary to removal of the hemisphere en bloc, hydrocephalus, and increased risk for sagittal sinus thrombosis.^{3,11} Hemispherectomy and hemispherotomy mortality rates range from 0 to 3.6%.^{12,15,33,34} The other complications are similar to those resulting from anatomical procedures; however, there is less blood loss and a decreased need for cerebrospinal fluid shunting.^{12,16,19,33} The reported rates for hydrocephalus range from 15 to 35% with anatomical hemispherectomy and from 2 to 16% with disconnective procedures.^{11,14,15,19,27}

75.4 Conclusion

Although hemispherectomy was initially developed for patients with cerebral tumors, it offers seizure freedom for patients with catastrophic epilepsy. There is a trend toward performing hemispherotomy procedures with minimal resection. However, with the anatomical modifications that can reduce the

risk for superficial hemosiderosis, hemispherectomy still holds value in selected cases in which ventricular access for a disconnection procedure is difficult because of the presence of a migrational disorder, such as hemimegalencephaly. It becomes a balance between surgical comfort with the procedure and the recognition that cerebrospinal fluid diversion may be required more frequently with anatomical procedures. Overall, as the surgical modifications continue to evolve and seizure freedom is obtained, consensus may be reached one day about which of the many procedures performed for catastrophic epilepsy in childhood holds the best promise for a good outcome and reduced morbidity.

Pearls

- Hemispherotomy can offer seizure freedom rates of 85 to 100% for patients with unilateral hemispheric intractable epilepsy.
- Commonly treated disorders include Sturge-Weber syndrome, cortical dysplasia, hemimegalencephaly, Rasmussen syndrome, porencephalic cyst, and hemiconvulsion-hemiplegia-epilepsy syndrome.
- It is imperative that all children for whom hemispherectomy or hemispherotomy is being considered undergo an evaluation by an experienced epilepsy team.
- Key anatomical details to identify on preoperative imaging include ventricular size, location of the circular sulcus, thickness of the corpus callosum, location of the pericallosal vessels, and abnormal vasculature.
- The literature supports performing surgery at an early age because of the plasticity of the younger brain.
- The key steps of a peri-insular hemispherotomy include supra- and infra-insular windows, temporal lobectomy, transection of the corona radiata, callosotomy, frontal disconnection, and insular resection.

76 Spasticity and Movement Disorders

A. Leland Albright

Although thousands of children have spasticity or other movement disorders, few pediatric neurosurgeons are involved in their care. That under-involvement partially reflects the paucity of neurosurgical treatments that were available historically. Until 1987, when Warwick Peacock and colleagues popularized selective dorsal rhizotomies,¹ pediatric neurosurgeons had little to offer children with spasticity. Since 1987, several methods for treating spasticity have become available, including oral medications (tizanidine), intramuscular (IM) medications (botulinum toxins), intrathecal medications (baclofen), and nonselective rhizotomies. Surgical options for treating dystonia and other movement disorders have increased with the introduction of intrathecal baclofen and deep brain stimulation. These options allow pediatric neurosurgeons to become involved in the care of a large group of children with whom we previously had minimal involvement, children whose quality of life can often be improved substantially.

The under-involvement of pediatric neurosurgeons in the care of children with spasticity or other movement disorders may also reflect a preference for not being involved in the treatment of severely disabled children and an uncertainty about how best to treat these complex patients. Much of their complexity is due to the fact that they often have more than one movement disorder; combinations of spasticity and dystonia, or of chorea and athetosis, are common, particularly in children with cerebral palsy (CP), and the most frequent cause of movement disorders in children is CP. Video examples of pediatric movement disorders are available on the WeMove Web site, <http://www.wemove.org>.

76.1 Spasticity

A task force defined spasticity as hypertonia in which one or both of the following signs are present: (1) resistance to externally imposed movement that increases with increasing speed of stretch and varies with the direction of joint movement, and/or (2) resistance to externally imposed movement that rises rapidly above a threshold speed or joint angle.² Clinically, spasticity may be defined as a velocity-dependent, increased resistance to passive muscle stretch. Strictly speaking, spasticity does not cause sustained, tonic increases of muscle tone, but rather increases in tone that vary according to movement, alertness, pain, and anxiety of the patient. Spasticity may be considered an isokinetic movement disorder because the amount of movement is not increased, as it is in hyperkinetic disorders like dystonia and chorea.

Spasticity is classified according to the limbs affected: spastic quadriplegia if all extremities are affected; spastic diplegia (or spastic paraparesis—the terms are synonymous) if the lower extremities are involved; spastic hemiparesis if an ipsilateral arm and leg are involved; and spastic monoparesis if only one limb is affected. Spasticity can affect trunk and cervical muscles, but no classification system grades their involvement. In Europe, children with spasticity that affects all extremities equally are said to have spastic tetraplegia, whereas those with more

severe involvement of the lower extremities than the upper are said to have spastic diplegia.

Spasticity has enormous clinical and economic implications. If untreated, it leads to progressive disability, discomfort, and deformity, and to multiple orthopedic operations to correct the deformities.

76.1.1 Epidemiology

Spasticity is common. It occurs in approximately 60% of individuals with CP (which occurs in 2.5 of 1,000 live births) and thus affects some 300,000 individuals younger than 18 years in the United States. The incidence of CP is not declining in the United States, probably because of the increased survival of low-birth-weight infants; the risk for CP is increased 25 to 30 times for those weighing less than 1,500 g.³ Spasticity also occurs in substantial numbers of children after serious head injuries and strokes, but the number with spasticity from those causes is unknown.

When spasticity occurs in association with CP, it is often not identified until 1 year of age or more. It may be more severe in the first 2 to 3 years of life, then improve as myelination increases. In a landmark study, Nelson and Ellenberg⁴ found that approximately two-thirds of children in whom spastic diplegia was diagnosed—and half of all children in whom CP was diagnosed at their first birthday—“outgrew” or lost the motor signs of the CP by their seventh year. Spasticity in CP may improve over time, and it does not worsen, although it may appear to do so for three reasons: increasing muscle strength, worsening contractures, and misdiagnosis (when worsening hypertonicity is due to dystonia rather than to spasticity). Spasticity that occurs in the first months after severe head injury is particularly likely to improve, so that permanent treatments, such as neurectomies, are infrequently appropriate during that year (although reversible treatments, such as botulinum toxin injections and intrathecal baclofen, may be appropriate).

76.1.2 Pathology and Pathophysiology

The pathophysiology of pediatric movement disorders was reviewed by Sanger in 2003.⁵ Muscle tone (the state of muscle contraction) is regulated by output from α motor neurons and is influenced by competing impulses: excitatory impulses, which enter the spinal cord via type Ia afferents from muscle spindles and cause the release of excitatory neurotransmitters, such as glutamate and aspartate; and descending inhibitory impulses from the basal ganglia and cerebellum, which cause the release of the inhibitory neurotransmitter γ -aminobutyric acid (GABA).⁶ Spasticity in humans is not due to increased gain of the muscle spindle, increased excitation of type Ia afferents, or increased γ efferents. There is probably reduced reciprocal inhibition of antagonistic motor pools by Ia afferents and decreased nonreciprocal inhibition by Ib terminals.⁷ Spasticity that develops in childhood differs somewhat from spasticity that develops in adults; early central nervous system (CNS) injury seems

more likely to result in a reorganization of corticospinal projections that leads to co-activation of agonist and antagonist muscle groups.^{8,9}

In simplistic terms, virtually all spasticity—whether of cerebral or spinal origin—can be attributed to an imbalance of excitatory and inhibitory impulses, with a relative deficiency of GABA in the spinal cord because of injury either to the developing brain or to the spinal cord conducting the descending inhibitory impulses. This pathophysiologic model also suggests two potential treatments: reducing the afferent excitatory input by rhizotomy and increasing the inhibitory neurotransmitter with a GABA agonist, such as baclofen. The paradigm also gives rise to the postulate that descending inhibitory impulses might be increased by cerebellar or spinal cord stimulation with implanted electrodes, treatments that were not effective.^{10,11}

76.1.3 Clinical Features and Grading

Symptoms of spasticity include muscle stiffness and tightness, fatigability, and pain. Pain often occurs during the night as a result of lower extremity muscle cramps or the inability to change positions. Spasticity in proximal lower extremity muscles causes progressive hip dislocation, which leads to acetabular deformity; this in turn may later cause intractable hip pain.

Spasticity typically involves certain muscles more than others; flexors and internal rotators are affected more than their antagonists. For children with spastic quadriplegia, that pattern of involvement results in the common stance of flexion at the elbows and wrists, with the child standing on the toes, the knees and hips somewhat flexed, and the legs internally rotated.

Spasticity associated with spinal cord injuries differs from cerebral spasticity in two ways: it is typically more severe because more descending inhibitory impulses are abolished, and it is more likely to be associated with painful muscle spasms. After spinal cord injuries, Ashworth Scale scores of 4 to 5, severe clonus, and muscle spasms are typical, whereas scores of 3 to 4 and less severe clonus are seen in cerebral spasticity. Clonus may be present at the ankle or knee and may occur spontaneously.

On examination, spasticity is usually evident exactly as it is defined, as a velocity-dependent, increased resistance to passive muscle stretch, so that as a joint is passively moved at vary-

ing rates, resistance varies. Spasticity is graded most commonly with the Ashworth Scale or Modified Ashworth Scale (► Table 76.1), based on the subjective grading of resistance to passive muscle stretch. Interrater reliability of the scale has been demonstrated.¹⁵ A less common method of evaluating tone is with the Tardieu Scale, although it is thought to provide a more accurate assessment than the Ashworth Scales (► Table 76.2).¹⁶ Spasticity is usually assessed with the child lying down, although a few children have dynamic spasticity, in which their tone is normal when they are lying down but increases when they stand or walk, especially tone in the adductors and plantar flexors.

When a child with spasticity is evaluated, it is important also to test the strength of the affected muscles because some children supplement weak voluntary muscle contractions with the involuntary muscle contractions of spasticity, so that gait and pivot transfers may worsen if spasticity is reduced. In children with spastic lower extremities, leg strength can be assessed by having them rise from a sitting position on a stool, by having them squat and rise in increments, and by having them stand on one foot at a time (Trendelenburg test); pelvic tilt to the lifted side indicates hip abductor weakness of the leg they are standing on.

If a muscle is affected by spasticity for several months, the muscle and its tendon undergo a permanent shortening—a musculoskeletal contracture—which is a fixed deformity that does not improve after treatment of the spasticity. Ideally, spasticity should be treated early to prevent the development of contractures, which occur most commonly in muscles that are affected most by spasticity: foot plantar flexors, knee flexors, and hip adductors.

Pediatric neurosurgeons who treat children with CP occasionally encounter some with hereditary spastic paraparesis (Strümpell-Lorrain disease), which is often misdiagnosed as CP.¹⁷ Hereditary spastic paraparesis is characterized by no history of perinatal asphyxia, normal intellect, slightly delayed motor milestones, and slowly progressive spastic paraparesis. A careful family history often uncovers symptoms in family members, although the extent of involvement may vary considerably from member to member. Neurosurgeons are also asked to see children in whom spastic CP has been misdiagnosed, but who have dystonia.

Table 76.1 Spasticity Scales

Ashworth Scale		Modified Ashworth Scale	
Score	Degree of muscle tone	Grade	Description
1	No increase in muscle tone	0	No increase in muscle tone
2	Slight increase in muscle tone, giving a “catch” when affected part is moved in flexion or extension	1	Slight increase in muscle tone
3	Moderate increase in muscle tone, passive movement difficult	1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of motion
4	Considerable increase in muscle tone, passive movements difficult	2	More marked increase in muscle tone through most of the range of motion, but affected part(s) easily moved
5	Affected part rigid in flexion or extension	3	Considerable increase in muscle tone, passive movement difficult
		4	Affected part(s) rigid in flexion or extension

Table 76.2 Tardieu Spasticity Scale

Velocities	
V1	As slow as possible, slower than the natural drop of the limb segment under gravity
V2	Speed of limb segment falling under gravity
V3	As fast as possible, faster than the rate of the natural drop of the limb segment under gravity
Scoring	
0	No resistance throughout the course of the passive movement
1	Slight resistance throughout the course of the passive movement, no clear catch at a precise angle
2	Clear catch at a precise angle, interrupting the passive movement, followed by release
3	Fatigable clonus with less than 10 seconds when the pressure is maintained and appearing at the precise angle
4	Unfatigable clonus with more than 10 seconds when the pressure is maintained and appearing at a precise angle
5	Joint immobile

Note: This test is performed with the child in the supine position, with the head in midline. Measurements are taken at three velocities: V1, V2, and V3. Responses are recorded at each velocity as X/Y, with X indicating the 0 to 5 rating and Y indicating the angle (in degrees) at which the muscle reaction occurs. If the limb is moved at different velocities, the response to stretch can be more easily gauged because the stretch reflex responds differently to changes in velocity.

76.1.4 Diagnostic Studies

No computed tomographic (CT) or magnetic resonance (MR) imaging characteristics are pathognomonic for spasticity, although MR images of children with spastic diplegia frequently demonstrate periventricular leukomalacia (► Fig. 76.1), and those of children with spastic quadriplegia often demonstrate multifocal, cystic encephalomalacia that involves both the cortex and underlying white matter. Neuroimaging features of spasticity and other movement disorders have been described.¹⁸

No methods are widely available to quantitate spasticity. Thus far, neurophysiologic techniques, such as H-reflex excitability curves and devices to measure velocity, joint angle, and torque, have not gained widespread clinical use. Electromyograms do not quantitate spasticity. In gait analysis studies, electrodes are applied to multiple lower extremity muscles; joint markers are applied to the hips, knees, and ankles; and children are videotaped while walking. Gait analysis allows a determination of which muscles contract during the gait cycle (frequently

identifying the simultaneous contraction of agonists and antagonists), stride length, cadence, and joint angles during the gait cycle. The interpretation of gait analysis is complex, but the resultant information is often helpful in planning subsequent orthopedic and neurosurgical intervention in ambulatory children. A complete discussion of gait analysis is beyond the scope of this chapter but is available in a publication.¹⁹

76.1.5 Treatment

It is important to remember that not all spasticity needs to be treated; spasticity that is mild, functionally useful, and neither interfering with function nor causing contractures can be left alone. If spasticity is to be treated, the treater and the treated should agree on the treatment goals. Common goals are to (1) improve function, (2) facilitate care, (3) retard or prevent the development of contractures, and (4) reduce or prevent pain. Patients commonly, and not unexpectedly, have higher hopes and expectations of treatment than do the treating physicians, despite careful preoperative discussions.

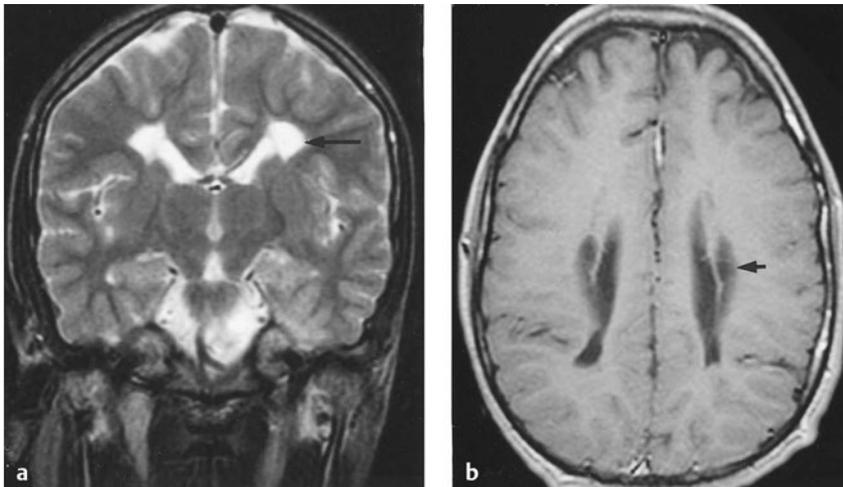

Fig. 76.1 (a) Axial and (b) sagittal magnetic resonance images demonstrating periventricular leukomalacia in a pediatric patient with spastic diplegia.

Spasticity can be treated with oral medications, intramuscular injections, intrathecal medications, and neurosurgical operations. The plethora of treatment options increases the dilemma for parents and patients and, to some degree, for physicians. Few centers have experience with all treatment modalities. Almost no good-quality studies have been done to evaluate the results of individual treatment modalities, much less to compare one modality with another. Ideally, children with spasticity should be evaluated in a multidisciplinary clinic that has experience in all treatment modalities. A gross motor function classification system (GMFCS) has been developed to classify function in children with CP so that the effects of treatments can be more readily compared.¹⁹

Treatment selection also varies according to the severity of the spasticity, the extent of the muscles involved, the age of the child, and the therapeutic goals, as discussed later. ▶ Table 76.3 lists the common treatments and their general indications.

Oral Medications

Three oral medications are thought to be useful in treating pediatric spasticity: baclofen, diazepam, and dantrolene^{12,20}; all act systemically and decrease spasticity diffusely. No study has compared their effectiveness, which is usually mild and often seems to wane over a few years. Medication dosages are listed in ▶ Table 76.3. For each medication, doses are adjusted to obtain the greatest therapeutic benefit with the fewest side effects. The use of oral medications for treating spasticity has been reviewed recently.²²

Baclofen (Lioresal; Novartis Pharmaceuticals, East Hanover, NJ), or chlorophenol GABA, is a GABA agonist that was synthesized to be an anticonvulsant (its antiepileptic activity was minimal). It is absorbed well and rapidly from the gastrointestinal tract, with peak serum levels 2 hours after a dose. The serum half-life is 3 to 4 hours. Baclofen is a racemic mixture whose site of action is the spinal cord, where primarily the levo-enantiomer acts both to decrease the release of excitatory neurotransmitters from type Ia fibers in superficial (Rexed layers I and II) layers of the spinal cord and to reduce postsynaptic impulses. Baclofen crosses the blood-brain barrier poorly; oral doses of 60 to 90 mg/d are usually associated with serum levels of 68 to 650 ng/mL, but with cerebrospinal fluid (CSF) levels of 12 to 95 ng/mL.²³ In a double-blinded crossover study of 15 children with spasticity and GMFCS levels of IV or V, children receiving baclofen scored significantly better on the goal attainment scale than those receiving placebo.²⁴

Diazepam (Valium; Roche Pharmaceuticals, Nutley, NJ) is a benzodiazepine receptor agonist that is also absorbed well and rapidly after oral administration. It crosses the blood-brain barrier moderately well and attaches to GABA_A and GABA_B receptors in the brain and spinal cord, so that it has a higher frequency of CNS side effects. Its half-life is 36 hours. It improves spasticity of children with CP, but effective doses frequently cause unacceptable sedation.²⁵ Dependence may develop after chronic administration, so that the drug should be discontinued slowly, often over months.

Tizanidine (Zanaflex; Acorda Therapeutics, Ardsley, NY), an α_2 -agonist, appears to modulate the release of excitatory neurotransmitters from interneurons and afferent terminals. Tizanidine was approved for the treatment of spasticity based on the

results of clinical trials of adult patients with spasticity from spinal cord injury or multiple sclerosis, in whom its effectiveness appeared to be similar to that of baclofen. A multicenter study of tizanidine in children with spasticity secondary to cerebral spasticity was recently concluded; the results have not been published as of September 2013.

Modafinil (Provigil; Cephalon, Frazer, PA) is a centrally acting stimulant that is thought to stimulate anterior hypothalamic nuclei. It was reported to improve spasticity in children with CP, but a subsequent double-blinded crossover study found that modafinil did not reduce spasticity or have a positive effect on quality of life.²⁶

Dantrolene (Dantrium; Procter & Gamble Pharmaceuticals, Cincinnati, OH) is the only medication to act at a non-CNS site, the sarcoplasmic reticulum, where it prevents the calcium influx necessary for muscle contraction and thus is less frequently associated with drowsiness or other CNS side effects. Its peak activity is 4 to 8 hours after administration. Although dantrolene has been reported to cause hepatotoxicity, usually after 3 to 12 months of treatment, severe hepatotoxicity rarely occurs in children younger than 10 years old, and fatal hepatotoxicity has not been reported in patients younger than 20 years old.²⁷

Baclofen is usually the first choice of oral agents. Doses are increased until improvement occurs, unacceptable side effects occur, or the maximum dose recommended for body weight is reached. If spasticity cannot be treated effectively with baclofen, it probably cannot be treated with other available agents used singly. Diazepam or dantrolene is occasionally given in combination with baclofen. Data comparing monotherapy with combination therapy are not available.

Neuromuscular Blockade

Neuromuscular blockade can be used to weaken muscle contractions, and thus spasticity, by interfering with nerve transmission, the neuromuscular junction, or muscle contraction. Medications available for IM injection include the following: botulinum toxin serotype A (Botox [Allergan, Irvine, CA]; Onabotulinumtoxin A—a purified version containing no extraneous proteins [Allergan]; Dysport [Ipsen, Slough, UK]); botulinum toxin serotype B (Myobloc; Solstice Neurosciences, South San Francisco, CA); phenol; and alcohol.^{28,29} No studies have compared their effectiveness. None treats spasticity per se; rather, they weaken the contraction of the injected muscle. IM injections are most appropriate for spasticity that affects localized muscle groups (e.g., plantar flexors and adductors) and are not appropriate treatment for generalized spasticity. However, for children with generalized spasticity, IM injections into the most severely affected muscles can be combined with oral medications that treat less involved muscles. Because the effects of IM medications usually wear off in a few months, such injections must be repeated and rarely provide a definitive treatment of spasticity. They are given with several goals: to decrease the spasticity of certain muscles (e.g., adductors) so that physical therapy can strengthen the antagonist muscles (abductors), to facilitate the serial casting of joints, and (rarely) to help determine if function of a limb would improve if spasticity were reduced. The use of injectable neuromuscular blockade to treat spasticity and other movement disorders was recently reviewed.^{30,31}

Table 76.3 Treatments for Spasticity

Method	Age (y)	Diagnosis	Characteristics	Expected results	Follow-up care	Outcome	Side effects, risk
Oral medications	Any age, most often 2 to 5	Spastic quadriplegia, traumatic brain injury	Diffuse spasticity	Mild decrease in spasticity in arms and legs	PT, OT as needed	SPRs or ITB often needed later	Drowsiness
Botox injections	Any age, less often older than 10	Spastic diplegia, spastic quadriplegia	Isolated spasticity; too young for ITB, SPRs	Decrease in spasticity in injected muscle(s) for 2 to 4 months	PT, OT to increase range of motion and to increase strength	Improved gait, sometimes improved arm function	None with usual doses
Rhizotomy (SPRs)	4 to 8 (most common), rare after 16	Spastic diplegia or quadriplegia, <i>capable</i> of ADLs	Good leg strength, no severe contractures, motivation for PT	Marked, permanent, nonadjustable decrease in spasticity	Extensive PT, OT	Improved walking, improved ADLs, decrease in orthopedic operations	Infection, 2%; wound, 1%; CSF leak, 3%
	Older than age 3, before multiple contractions	Spastic diplegia or quadriplegia, <i>not capable</i> of ADLs	Severe leg spasticity interfering with care		Minimal	Easier care	Infection, 2%; wound, 1%; CSF leak, 3%
Baclofen (ITB)	Older than age 3, big enough to insert pump	Spastic quadriplegia, spasticity in legs greater than or equal to spasticity in arms, <i>capable</i> of ADLs	Severe spasticity, positive response to test dose, spasticity limiting function	Adjustable decrease in spasticity	Frequency of PT, OT depends on goals	Improved walking, improved ADLs, improved speech, decrease in orthopedic operations, easier care	Infection, 5 to 10%; wound, 5 to 10%; CSF leak, 5 to 10%
		Spastic quadriplegia, <i>not capable</i> of ADLs	Spasticity interfering with care		Minimal PT	Easier care	
		Posttraumatic brain injury	Severe spasticity in arms or legs, usually more than 1 year after injury		PT, OT for range of motion		

Abbreviations: ADLs, activities of daily living; CSF, cerebral spinal fluid; ITB, intrathecal baclofen; OT, occupational therapy; PT, physical therapy; SPRs, selective posterior rhizotomies.

Botulinum toxin acts at the neuromuscular junction to prevent the release of acetylcholine. There are seven botulinum neurotoxins (A through G), two of which are commercially available. Botox is type A, the most potent serotype; Myobloc is type B. Botox is injected directly into muscle; its effect commences within 1 to 3 days, is maximal at 21 days, and wanes—perhaps because of the development of new neuromuscular junctions—by 3 to 4 months afterward, when the injections can be repeated. Doses depend on the size of the muscle to be injected and on the severity of its spasticity. In the lower extremities, Botox is often injected into spastic gastrocnemius, hamstring, and adductor muscles. If injections are needed into muscles that are difficult to locate by palpation, such as the pronator teres or posterior tibial muscle, electrical stimulation will identify the desired injection site.

The maximal recommended Botox dose at present is 10 U/kg, although I, and others, have used 20 to 25 U/kg without adverse effects. The drug comes as a precipitate in vials of 100 U, is diluted to 10 U/0.1 mL or 10 U/0.2 mL, and injected into muscles at one to several sites. Dysport, the form of botulinum toxin available in the United Kingdom, is now available in the United States. It has approximately one-third the potency of Botox, and doses are accordingly higher.

The effects of Botox—alone or in combination with occupational therapy—on the upper extremities of children with spastic CP were evaluated in a 2010 Cochrane Systematic Review of 10 randomized controlled trials (RCTs).³⁰ The combination of Botox and occupational therapy was more effective than occupational therapy alone in reducing impairment and improving activity-level outcomes, but not for improving quality of life. There was moderate evidence that the use of Botox alone was not effective. The effects of Botox on lower extremity spasticity and gait have been evaluated in recent reviews of RCTs. Boyd and Hays reviewed 10 RCTs and concluded that Botox had a moderate, dose-dependent effect on gait and lower limb function.³¹ Koog and Min reviewed 15 RCTs and concluded that botulinum toxin serotype A (BtxA) was little better than a sham control.³² Ryll et al reviewed 8 RCTs that compared BtxA plus usual care or physiotherapy versus physiotherapy alone.³³ The studies showed moderate evidence for improved functional outcomes—mainly walking—at 2 to 24 weeks for those receiving BtxA, but no difference between BtxA and casting. BtxA treatment of ambulatory children with spastic CP has been shown to improve gait analysis parameters and to reduce oxygen consumption.³⁴

Treatment with IM injections provides temporary improvement of spasticity and thus may be considered as a bridge to more definitive treatments. I often use Botox repeatedly in patients from age 2 years until age 5 or 6 years, by which time it is usually apparent whether the child will need longer-term treatment, such as a rhizotomy or an intrathecal baclofen pump. Only a few children who are treated with Botox in the 2- to 5-year interval improve enough that no subsequent intervention is needed. Children almost never develop immunity to Botox; the preparations that have been available in recent years are more purified and lack the protein to which early subjects occasionally developed antibodies.

Botox is tightly bound to the neuromuscular junction and a minimal amount enters the systemic circulation, so that systemic side effects are uncommon after injections into extremity

muscles. Those effects include flulike symptoms, generalized weakness, dysphagia, and aspiration. In 2008, the Food and Drug Administration (FDA) reported that children treated for spastic CP had rarely developed serious side effects consistent with botulism.³⁵ In a subsequent meta-analysis of 20 RCTs and 882 subjects who had received BtxA, a variety of symptoms were reported, including muscle weakness, urinary incontinence, fever, falls, and pain.³⁶ Two deaths were reported but were thought to be unrelated to BtxA, and the authors concluded that BtxA had a good short-term safety profile. Despite the FDA warning, the use of BtxA remains widespread.

One circumstance in which Botox injection is probably underused is in children with severe head injury in whom gastrocnemius spasticity causes severe plantar flexion of the feet within weeks after injury. The plantar flexion is usually treated ineffectively by serial casting, and children typically develop plantarflexion contractures that require orthopedic releases. Posttraumatic spasticity often abates within 6 to 12 months, but by then, contractures have developed. The injection of BtxA into the affected muscles early after injury, as soon as significant spasticity is detected, should minimize such contractures, particularly if combined with ankle casting.

Phenol and alcohol can be injected directly into spastic muscles, where they cause focal muscle necrosis, or at the myoneural junction. Injections are painful, cause muscle soreness for several days, and are usually performed in children under a brief anesthetic. IM injections of 50% alcohol, 5 mL at one to three sites, or perineural injections of 5% aqueous phenol are common. Weakness of the injected muscle develops over several days and persists for weeks to months. Because of the pain and dysesthesias associated with their use and the variable responses obtained, phenol and alcohol are used much less frequently since the availability of Botox. However, because alcohol and phenol are far less expensive than Botox, and their effects persist longer, they are preferred in some centers to treat spastic muscles innervated by motor nerves, and they remain the injectable option of choice in developing countries.

Intrathecal Medications

Intrathecal baclofen (ITB) is by far the most common medication to be infused intrathecally, although morphine, fentanyl, tizanidine, and clonazepam have been used.

ITB is more effective than oral baclofen because the CSF concentration of baclofen obtained after intrathecal injection is so much higher than that after oral administration (400 ng/mL in a patient receiving 396 µg of ITB per day versus less than 12 ng/mL in a patient receiving 60 mg of oral baclofen per day).²³ After a single ITB dose, spasticity in the lower extremities begins to diminish in 2 hours, is maximally reduced in 4 hours, and recurs in 8 to 10 hours.³⁷ The half-life of an intrathecal dose is 4 to 5 hours.³⁸ ITB is cleared at a rate of 30 mL/h, the rate of CSF clearance. After baclofen infusions in the region of the conus medullaris, lumbar CSF concentrations are approximately fourfold higher than those at the cisterna magna.³⁹ These data suggest that the position of the catheter tip should vary according to whether spastic diplegia or quadriplegia is being treated.

ITB is effective in treating spasticity of spinal or cerebral origin. It diminishes stretch reflex excitability and abnormal muscle co-contractions that occur in children with cerebral

spasticity.^{40,41} ITB has been used to treat children and adolescents with spinal spasticity due to trauma, transverse myelitis, arteriovenous malformations, or familial spastic paraparesis.⁴²

We conducted a prospective study of long-term ITB in 37 children with cerebral spasticity that was mostly due to CP but also due to head injury or ischemia.⁴³ We found that ITB reduced spasticity in the lower and upper extremities and that improvement occurred in hamstring range of motion and in position transitions. Improvement was also noted on an activities-of-daily-living scale that assessed communication, dressing, positioning, and feeding. Since then, multiple studies have confirmed the effectiveness of ITB in reducing spasticity, in improving motor function as evaluated by the Gross Motor Function Measure (GMFM), and in improving comfort and caregiving.^{44–46}

Until recently, a test dose of ITB was always given to confirm the child's response to ITB before a pump was implanted. As hundreds of children have been tested with bolus injections, it has become apparent that almost all respond to the bolus doses if they have spasticity (but not dystonia or contractures). Additional reasons not to do a test dose are that the customary doses, 50 to 100 µg, are excessive and result in extreme hypotonia of the lower extremities, in addition to the headache and vomiting that commonly occur after lumbar puncture. Thus, increasing numbers of centers that have experience with bolus doses and patient selection are forgoing the test injections and proceeding directly to pump implantation.

In children with spasticity and ventriculomegaly who may need a pump, it is important to consider a lumbar puncture to measure the opening pressure before a pump is inserted. Many children with spastic CP have had intraventricular hemorrhages as infants and have chronic ventriculomegaly and increased opening pressures.⁴⁷ If such pressure is not addressed, it increases the risk for CSF leaks around the intrathecal catheter if a pump is subsequently implanted.

ITB is usually administered by a programmable pump implanted subcutaneously or subfascially in the abdomen and connected to a catheter that is tunneled subcutaneously posteriorly to the lumbar region, then via a Tuohy needle into the CSF. Nonprogrammable pumps are available but do not allow the frequent dose adjustments that are needed in the first 1 to 2 years when cerebral spasticity is being treated. Pumps are programmed to deliver doses of baclofen that are adjusted according to the goals of treatment. SynchroMed II pumps (Medtronic, Minneapolis, MN) have 20- or 40-mL reservoirs. The 20-mL pump is small enough to be inserted into children weighing 10 kg. When pumps are implanted into small, thin children, healing appears to be better if the pumps are implanted below the abdominal fascia.

The main risks of pump implantation are infection, CSF leakage, and catheter problems, such as breaking and cracking.⁴⁸ The risk for each is approximately 5 to 10%. Borowski et al reported a 31% complication rate requiring surgical management over a 3-year period in 316 surgical procedures.⁴⁹ If a pump infection occurs, some neurosurgeons have attempted to "save" the system by irrigating or debriding the wound and giving intravenous antibiotics for 2 to 3 weeks. In my experience, the likelihood of success with that technique is small.

ITB doses typically increase during the first year after implantation, then remain relatively stable. If a child has had good

results from ITB for 1 to 2 years and then the effects wane despite increasing doses, there is almost always a problem with the catheter infusion system, not the pump. The current Medtronic pump battery lasts approximately 7 years before replacement is necessary. After a child has received ITB for several months, it should not be withdrawn abruptly. Withdrawal symptoms of itching, agitation, and spasms are common; seizures and fever may occur; and severe symptoms, such as hyperthermia, psychosis, and multiple-organ failure, have been reported.^{50,51} Children presenting with signs and symptoms of ITB withdrawal must be given large doses of oral baclofen, evaluated urgently, and have the malfunction repaired promptly.⁵²

Side effects of ITB include listlessness, hypotonia of the trunk and neck, and occasional urinary hesitancy, symptoms that subside with reduction in dosage. ITB does not appear to increase the frequency of seizures. In a multicenter study of ITB in 68 children, seizure frequency was increased in none of the children.⁵³ Overdoses, which are rare during routine treatment, cause profound muscle hypotonia and lethargy. Treatment of severe overdoses includes artificial ventilation, stopping the pump, and CSF barbotage. The drug is not toxic, and ITB infusion usually resumes after the overdose clears in 1 to 2 days.

Advantages of ITB therapy are that it is highly effective in reducing spasticity in the arms and legs and often improves global function. Furthermore, the dose can be titrated to obtain the desired reduction in spasticity, and ITB is nondestructive. Its disadvantages are the costs of the pump, implantation, and refills, and the complications of the infusion system.

Rhizotomies

Ventral (motor) rhizotomies were described for adults with spasticity in 1932, but they fell out of favor because of muscle atrophy and the resultant loss of function.⁵⁴ They have no place in the current treatment of pediatric spasticity. The neurophysiologist Sherrington⁵⁵ laid the foundation for dorsal rhizotomies. He treated the "spasticity" that resulted after sectioning the midbrain of cats with rhizotomies of the cervical dorsal roots and found that their hypertonia was abolished. Parenthetically, they probably had extensor rigidity rather than spasticity. Based on that laboratory work, Foerster⁵⁶ performed L2–S1 rhizotomies, sparing L4, in 153 children with cerebral spasticity and reported excellent results. The procedure was not used thereafter for several decades, probably because of the sensory loss and ataxia that would occur if the entire sensory roots of L2, L3, L5, and S1 were divided.

In 1978, Fasano et al⁵⁷ reported their use of selective dorsal rhizotomy (SDR). They stimulated the lumbar posterior roots of children with CP at various rates (1 to 50 Hz) and found that the stimulation of "normal" roots at 50 Hz caused a brief muscle contraction followed by relaxation, but that stimulation of "abnormal" roots caused a tetanic contraction that often persisted after the stimulus ceased. They divided the rootlets that generated the "abnormal" response and reported good relief of lower extremity spasticity in 71% of cases, with return of spasticity in approximately 5% of cases in the following years. This procedure was modified and popularized by Peacock et al, who identified as "abnormal" features tetanic responses, responses that persisted after the stimulus ceased, clonus, contraction of muscles in the contralateral extremity, and contraction of

muscles not normally in that myotome.¹ They also performed the testing and division of the nerves at their exit zones from the dural sac, where they could be identified more readily than at the point where they entered the conus medullaris. Park and Johnston subsequently advocated dorsal rhizotomies at the conus, via limited laminotomies, and reported equally good outcomes.⁵⁸ Ou et al compared outcomes after single-level laminotomies at the conus versus multilevel lumbar laminectomies and found no differences in outcomes other than shorter hospitalizations after the single-level procedure.⁵⁹

There is continued controversy about the validity of the neurophysiologic criteria used to distinguish normal and abnormal responses. It appears that tetanic contractions, which were considered abnormal, are a normal response to a 50-Hz stimulus. Investigators have demonstrated that there is considerable variability in response patterns to repetitive stimuli.^{60–62} Some of the response variability may be attributable to whether stimulation is performed with constant current or constant voltage. Because tetanic responses are not considered now to be abnormal, the proportion of nerve rootlets divided has decreased (without a decrease in effectiveness), and the frequency of postoperative hypotonia has diminished.

Many neurosurgeons now perform lumbar dorsal rhizotomies without using neurophysiologic monitoring and base the percentage of dorsal roots to be divided on the preoperative clinical examination. Steinbok et al compared the outcomes of 22 patients who had lumbar dorsal rhizotomies without electrophysiologic guidance and the outcomes of 22 patients who had lumbar dorsal rhizotomies with electrophysiologic guidance, and they found no differences in spasticity reduction or any other parameters.⁶³ I used monitoring for perhaps 15 years, but for the past 7 years I have used no monitoring and have observed no difference in spasticity outcomes.

The critical aspect of SDR is not electrical stimulation, but rather patient selection. Good candidates for SDR are usually 5 to 8 years old with spastic diplegia that is inhibiting their gait; they have good strength in their legs, and mild contractures. Few children with CP meet these criteria. Functional decline in children undergoing SDR after age 10 has recently been reported.⁶⁴ Dorsal rhizotomies do not improve dystonia, although they are performed relatively often in children with unrecognized dystonia, nor do dorsal rhizotomies reliably improve spasticity in children with familial spastic paraparesis.

Children treated by Peacock's method have significantly decreased spasticity in the lower extremities, improved range of motion, and improved gait, with longer stride length and faster cadence. McLaughlin et al⁶⁵ performed a meta-analysis of data from three RCTs of SDR. Spasticity was significantly decreased, and function, as evaluated by the GMFM, was significantly improved. Although SDR has been reported to decrease the development of musculoskeletal deformities and contractures, more recent publications indicate that many children will require orthopedic operations.^{66,67}

Although some series report a regression of the GMFM to baseline values 10 years after SDR, most studies report persistent improvement in GMFM and GMFCS levels.^{66–68} Two of the best long-term evaluations of SDR, from Peacock's original group, found that 20 years after SDR, a prospective gait analysis in 13 patients showed improved locomotor function and

improvements in the GMFCS levels.^{69,70} Spasticity, stride length, and quality of gait may also improve after SDR in children with spastic hemiparesis.⁷¹

Cervical SPR has been performed to treat spasticity of the biceps and of the wrist and finger flexors, which results in contractures and poor hygiene.⁷² In my experience, cervical SDR improves spasticity in the upper extremities approximately as well as lumbar SPR improves spasticity in the lower extremities, but upper extremity function is less likely to improve. Cervical SDR is infrequently performed, mainly because of the availability of treatment alternatives such as IM injections, peripheral neurectomies, and orthopedic operations.

Peripheral Neurectomies

Peripheral neurectomies have been used in Europe and India more often than in the United States and are an underutilized operation. Like IM injections, they do not reduce spasticity per se but rather weaken contraction of the muscle. Thus, they are performed to treat focal spasticity rather than generalized spasticity. Spasticity in the plantar flexors, hip adductors, and elbow flexors is treated by peripheral neurectomies of the posterior tibial, obturator, and musculocutaneous nerves, respectively.⁷³ The procedure is performed to increase range of motion, facilitate care, and lessen the development of contractures, rarely with the goal of improving function. It is performed under general anesthesia and can be done either nonselectively, dividing 50 to 80% of the nerve, or selectively, with intraoperative stimulation of nerve fascicles to identify motor branches whose stimulation results in strong muscle contractions. Selective motor fasciculotomy for spastic upper extremities was reported for 20 patients whose mean age was 13 years.⁷⁴ Fasciculotomies of the musculocutaneous, median, and ulnar nerves reduced spasticity of the affected muscles and improved self-care.

Treatment Selection

Given the plethora of methods available to decrease spasticity, both those who treat and those who receive treatment may be perplexed. It is important to remember that not all spasticity needs to be treated, and that treatment goals should be carefully identified before any therapy is undertaken. The reasons for not needing to treat all patients with spasticity include the following: (1) Some mild spasticity causes no interference with function and no orthopedic problems. (2) Some spasticity is clinically useful in individuals with weak extremities, to augment contractions of weak muscles. (3) Spasticity that causes extremity stiffness may help maintain an erect posture of the neck and trunk; if it were treated, the arms and the legs might relax, but the child might then be unable to hold the head up or to sit upright.

In general, treatment goals include improving function, facilitating care, preventing or minimizing contractures, and, infrequently, reducing painful muscle spasms or cramps. The goal of improving function may include general goals such as easier ambulation, dressing, or transfers, but unfortunately, more specific goals such as improved handwriting or swallowing cannot be predicted. In my experience, upper extremity function improves in approximately 60% of children with spastic quadriplegia after ITB, and speech intelligibility and swallowing

improve in approximately 40%, but I know of no way to predict which children will have such improvement; screening trials do not answer the question.

Treatment selection also depends on the severity of the spasticity, the extent of involvement (focal or diffuse), and the child's age. Muscle tone with a score of 2 on the Ashworth Scale is mild and usually does not need to be treated; tone with a score of 3 to 5 usually does. Oral medications are of minimal, if any, help in treating severe spasticity. Focal spasticity is more appropriately treated with botulinum toxin injections than is diffuse spasticity.

Age is important for the following reasons: (1) Ablative procedures like SPR are usually delayed until the age of 4 to 5 years because brain maturation (and a decrease in spasticity) may occur by that time. (2) Children younger than 4 years are infrequently candidates for ITB pumps; their spasticity can usually be treated satisfactorily with oral medications and botulinum toxin. (3) SPR is infrequently performed in children older than 16 years if the goal is to improve function because their ability to strengthen weak muscles and to learn new gait patterns is more limited than that of younger children. Ablative procedures are more commonly performed in children for whom the treatment goal is to facilitate care rather than to improve function.

For children 1 to 4 years old with diffuse spasticity, treatment usually entails oral spasmolytics, which usually reduce Ashworth Scale scores from 3 or 4 down to 2. However, the score is infrequently reduced to normal, and infrequently to a degree such that the child no longer exhibits plantar flexion of the feet or scissoring (adduction) of the legs; botulinum toxin is often injected into those muscles to prevent contractures that might otherwise develop despite the oral medications.

The age at which SPR is performed varies according to the treatment goal: if improved ambulation is the goal, SPR is performed most commonly in children 5 to 8 years old but is infrequently performed after age 12. If the goal is to facilitate care and age is not an issue, the operation can be done at any time, preferably before contractures develop. If the goal is to facilitate the care of children with spastic quadriplegia (whose spasticity involves the lower extremities more than the upper), lumbar SPR is probably the best treatment—it is definitive and effective. Of children with spastic quadriplegia that involves the upper and lower extremities equally, those who are functional are probably best treated by ITB and those who are nonfunctional either by ITB or by combined cervical and lumbar dorsal rhizotomies.

ITB is useful in ambulatory children who have some leg weakness because doses can be increased slowly as muscle strength improves. ITB is probably not helpful in improving the ambulation of patients with spastic diplegia who are in their late teens or older because of their limited ability to improve their strength and learn new gait patterns, although it may improve trunk and upper extremity mobility and function in that age group. ITB is also appropriate for children with spastic paraparesis after spinal cord injuries. For those with *nonfamilial* spastic paraplegia, either SPR or ITB may be used; SPR is probably preferable because of its lower complication rate. Children with spastic quadriplegia after spinal cord injuries are usually treated with ITB.

Peripheral neurectomies may be considered in children with focal spasticity that has not yet caused substantial

contractures. The children have usually been given repeated botulinum toxin injections for 1 to 3 years but need therapy that is more permanent.

76.2 Dystonia

Dystonia has been defined as "... a movement disorder in which involuntary sustained or intermittent muscle contractions cause twisting and repetitive movements, abnormal postures, or both."² Dystonia is classified according to the body regions involved: focal if one region (such as one upper extremity) is involved, segmental if adjacent regions (such as the neck and upper extremity) are involved, hemidystonia if one side of the body is affected, and generalized if the entire body is affected. Dystonia is also characterized as primary or secondary: primary if no underlying pathology can be identified and the individual shows no other neurologic abnormalities, and secondary if the dystonia can be attributed to a structural cause (such as a lesion of the basal ganglia). Some clinicians add a third category, hereditary. The term *primary dystonia* is synonymous with the previously used term, *dystonia musculorum deformans*. Whether primary or secondary, dystonia is characterized by simultaneous contractions of agonist and antagonist muscles, and to a considerably greater extent than occurs in spasticity.

Primary dystonias are diagnosed by genetic analysis. At present, 21 different abnormalities in the *DYT* (TORIA) gene have been identified, causing disorders such as early-onset primary dystonia (*DYT1*), X-linked dystonia-parkinsonism ("Lubag," *DYT3*), dopa-responsive dystonia (Segawa syndrome, *DYT5*), and myoclonic dystonia (*DYT11*). Secondary dystonias are diagnosed most often by abnormalities in the basal ganglia, particularly the putamen. Hereditary dystonias may be caused by Huntington disease, Wilson disease, neuroacanthocytosis, Rett syndrome, Leigh disease, and neurodegeneration associated with iron deposition (Hallervorden-Spatz disease, PKAN [pantothenate kinase-associated neurodegeneration] disease), and are diagnosed by tests specific for each of those disorders.

Pediatric neurosurgeons encounter dystonia frequently in children with CP, occasionally after head injury, stroke, or tumor removals; uncommonly in children with hereditary dystonias; and rarely in children with primary dystonia. CP usually causes generalized dystonia but occasionally hemidystonia or dystonic paraparesis, whereas stroke or head injuries are more likely to cause focal dystonia or hemidystonia and to follow an initial hemiplegia. In the series of Saint Hilaire et al,⁷⁵ no patient with CP had focal dystonia. Posttraumatic dystonia usually occurs after severe head injuries but may follow minor injuries, and in either case it may develop months to years after the injury and may worsen for a few years before stabilizing.⁷⁶ As a general rule, dystonia that develops several years after an injury or an ischemic event is less likely to be severely disabling than dystonia that begins soon afterward.

76.2.1 Epidemiology

Primary dystonia occurs most frequently in Ashkenazi Jews, affecting 1 per 3,000 to 1 per 9,000 in that population. In non-Jewish people, the incidence ranges between 1 per 10,000 and 1 per 30,000. Secondary dystonia is far more common, occurring in 15 to 25% of individuals with CP.

76.2.2 Clinical Presentation

Dystonia associated with CP may not be clinically evident until 3 to 15 years of age, perhaps because a certain degree of myelination is necessary before the dystonic movements can become apparent.⁷⁷⁻⁷⁹ Dystonic movement in CP may cause the extremities to writhe in random motions or to contract repeatedly in abnormal postures. Dystonia may cause intermittent deviation of the head to one side, posterior arching of the neck and trunk, and intermittent extension or adduction of the upper and lower extremities. The movements are not stereotypic, as are the abnormal postures seen in infancy (e.g., the asymmetric tonic neck reflex). Dystonia is increased by excitement and ceases with sleep. Dystonic children are typically thin because of the calories expended during sustained muscle contractions, and they have muscles that are well developed because of repeated isotonic contractions. Although the brain lesions in CP are static, the dystonic movements may worsen over several years.

Primary dystonia in children is graded most frequently with the Burke-Fahn-Marsden (BFM) Dystonia Rating Scale, which was developed to grade primary dystonia in adults.⁸⁰ Secondary dystonia is graded with either the Barry-Albright Dystonic (BAD) Scale, which was developed and validated for use in children with secondary dystonia, or with the BFM Scale.⁸¹

Dopa-responsive dystonia (Segawa disease) may be misdiagnosed as dystonic CP.⁸² Dopa-responsive dystonia begins during childhood, often with gait difficulties or as dystonia in a foot. It has diurnal variations in 75% of cases and frequently a positive family history, and it may be associated with spasticity or Parkinsonian features. Dopa-responsive dystonia responds dramatically and chronically to low doses of levodopa, without the dyskinesia that occurs in adults treated with levodopa.⁸³ A trial of levodopa should be considered in children with dystonia unless they have an unequivocal historical and radiographic features of CP.

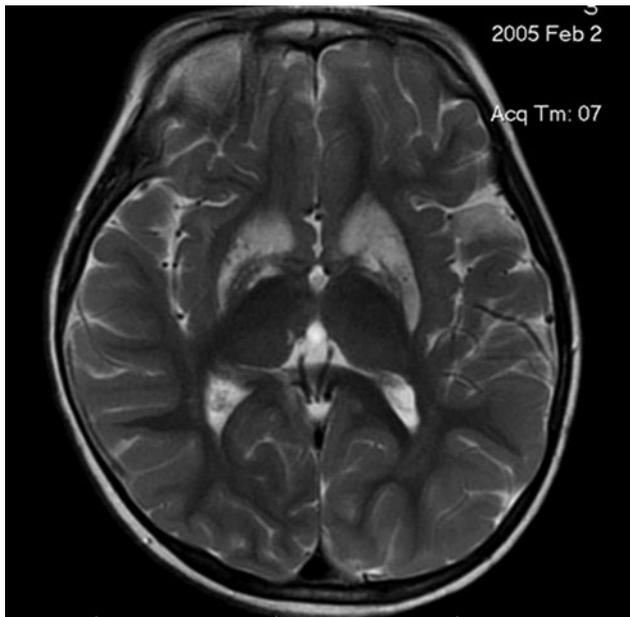

Fig. 76.2 Axial magnetic resonance image demonstrating caudate and putaminal changes associated with generalized secondary dystonia.

76.2.3 Pathology and Pathophysiology

There is no demonstrable pathology in primary dystonia. Secondary dystonias and some hereditary dystonias are associated with lesions in the basal ganglia, particularly in the caudate and putamen (► Fig. 76.2 and ► Fig. 76.3).

Cortical motor excitability appears to be increased in dystonia.⁸⁴ Positron emission tomography (PET) in adults with primary dystonia demonstrates overactive prefrontal and underactive motor cortical areas, consistent with inappropriate overactivity of the striatofrontal projections and underactivity of the primary motor areas.^{15,85} Recent experimental and clinical studies have shown reduced spontaneous activity in both the internal and external segments of the globus pallidus, with bursts and pauses, and reduced output from the internal globus pallidus, which may increase thalamic and cortical activity.⁸⁶

76.2.4 Treatment

Oral Medications

In general, oral medications are mildly to moderately helpful in treating both primary and secondary dystonia, and they are more helpful in younger children than older ones. ► Table 76.4 lists the commonly used agents. In treating secondary dystonia in children, baclofen (Lioresal) and trihexyphenidyl (Artane; Lederle Pharmaceuticals, Carolina, PR) are the first two drugs of choice.^{87,88}

Intramuscular Medications

Although botulinum toxin has not been approved by the FDA for use in children with dystonia, it has been approved for use in adults with focal dystonia (torticollis, blepharospasm) and is being used to treat many children with dystonia, both in clinical

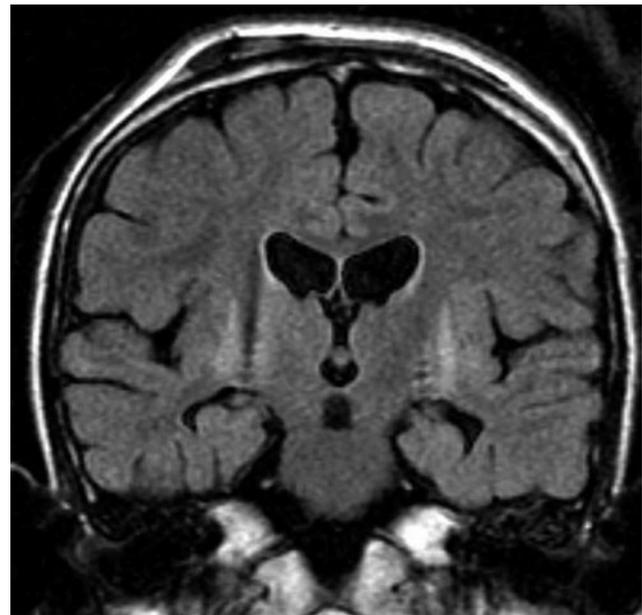

Fig. 76.3 Bilateral deep brain stimulation electrodes implanted into the internal globus pallidus to treat an adolescent with generalized dystonia.

Table 76.4 Oral medications for dystonia

Medication	Mechanism of action	Half-life (h)	Initial dosage	Maintenance	Side effects
Baclofen (Lioresal)	GABA _B agonist	3–4	2.5–10 mg/d	20–90 mg/d divided into 3 doses	Drowsiness, ataxia, confusion
Diazepam (Valium)	Benzodiazepine receptor agonist	36	0.1–0.2 mg/kg/d	0.1–0.8 mg/kg/d divided into 3 doses	Lethargy, tolerance
Dantrolene (Dantrium)	Impedes muscle contractility	3–9	0.5–1 mg/kg/d	12 mg/kg/d divided into 4 doses	Weakness, diarrhea, rash
Tizanidine (Zanaflex)	α ₂ -Adrenergic agent	2–3	4–8 mg/d	8–24 mg/d divided into 4 doses	Sedative, dizziness, hypotension

Abbreviations: GABA_B, γ-aminobutyric acid B-receptor.

research protocols and off label. Although botulinum toxin has been beneficial in treating adults with focal dystonias, such as torticollis and limb dystonias,^{89,90} its usefulness in children is somewhat limited to those with hemidystonia, in which injections into the affected muscles may not only decrease the dystonic movements but also improve hand and arm function and foot posture. Doses used for dystonic extremities are restricted by body weight; doses of 10 to 20 U/kg are commonly given.

Intrathecal Medication

In 1992, Narayan et al⁹¹ reported the first use of ITB for dystonia, in an 18-year-old with axial dystonia after a cerebral injury at birth. Baclofen is the only intrathecal medication that has been reported to improve dystonia. Its site of action in doing so is unknown. Several clinical features suggest an intracranial (cortical) site of action, with inhibition of the excessively stimulated premotor and supplementary motor cortex.⁹² However, Dachy and Dan⁹³ found motor evoked potentials to be preserved and the H-reflex to be inhibited after ITB, observations that are more consistent with a spinal site of action.

Penn et al⁹⁴ treated 10 adults with various motor disorders and observed improvement in those with focal dystonias. We have used ITB to treat generalized dystonia in more than 300 children during the past 15 years, primarily children with secondary dystonia and a few with hereditary degenerative dystonia. We have found that dystonia is significantly improved in 85 to 90%, ease of care and comfort are improved in 85%, and speech and function are improved in one-third.⁹² We observed several differences compared with the use of ITB in spasticity. First, dystonia often does not respond to bolus screening doses, so if screening is to be done, a continuous infusion via an intrathecal catheter connected to an external microinfusion pump is appropriate. Second, the doses to which dystonia responds are higher than those used for spasticity; dystonia usually responds to doses of 400 to 600 μg/d, although doses of 1,000 μg/d or higher may be needed. These high doses are not associated with lethargy or other CNS side effects. The response rate of children with generalized secondary dystonia to ITB is similar to the response rate of children with spasticity. Because of that, we now usually do not screen response to ITB before implanting a pump for dystonia. However, if a child has a combined movement disorder (e.g., a mixture of dystonia, chorea, and athetosis), an infusion trial to evaluate the response is indicated.

Although children with spasticity retain their responsiveness to ITB for many years, it appears that perhaps 10% of children

with dystonia lose their responsiveness to chronic ITB infusion during the first 1 to 2 years of therapy. Overall, however, ITB offers far better treatment of severe secondary generalized dystonia than any oral medication, and probably better than any currently available operation. Children with dystonia associated with glutaric aciduria also respond to ITB, although not as well as children with secondary dystonia; they do not seem to respond to deep brain stimulation. Children with generalized dystonia have significant improvement in dystonia in all body regions after continuous ITB. Experience with ITB for primary dystonia is limited, but thus far, ITB appears to bring about no significant improvement.

Since the publication of the second edition of this text, ITB infusions in children with secondary dystonia have been reported to significantly improve both upper limb function and dystonia, and to improve individually identified functional goals, caregiver burden, and pain.^{95–97} In addition, baclofen infusion has been extended to the intraventricular route, which appears to achieve a reduction in dystonia similar to that seen with the intrathecal route, to have a similar complication rate, and to cause fewer catheter complications.^{98–100}

Stereotactic Procedures

Because dystonia in children often worsens for a few years before stabilizing, permanent and nonadjustable procedures such as thalamotomies are usually deferred until dyskinesia has stabilized. Because of this, there are few published reports describing the results of thalamotomies for children with hyperkinetic movement disorders.^{101,102} Speelman and van Manen¹⁰³ reported that 8 of 18 patients who had CP treated with stereotactic thalamotomies showed improvement at a mean of 21 years after operation. Posttraumatic dystonia is often temporarily improved by stereotactic thalamotomies, but the dystonia may worsen later. Pallidotomies are being tried, but outcome data in children are sparse. Pallidotomy has been reported to improve dystonia in a child with Huntington disease.¹⁰⁴ In primary dystonia, 60 to 80% improvements in the BFM Dystonia Scale have been reported after pallidotomy.

Deep brain stimulation (DBS) is a potential treatment for children and adolescents with severe dystonia that is unresponsive to oral medications. DBS appears to act like a lesion, interrupting the abnormal cortical–basal ganglia–cortical loop that generates the dystonic movements. For children with primary dystonia, DBS is the preferred treatment after oral medications; for those with secondary dystonia, ITB is probably the best

treatment after oral medications, with DBS reserved for those who do not respond to ITB.

Coubes et al¹⁰⁵ published the first substantial series of dystonic children treated with DBS. They reported that in 25 children with primary dystonia, BFM Dystonia Scale scores improved by 80 to 84%, and that the improvements persisted for 2 years or longer. In 10 children with secondary dystonia, the BFM Dystonia Scale scores improved by 31%.¹⁰⁵ Air et al recently reported their results of DBS for various types of dystonia; in 13 children with primary dystonia, the BFM Dystonia Scale scores improved by 75%, but in 18 children with secondary or heredo-degenerative dystonia, the scores improved by only 10 to 20%.¹⁰⁶ Haridas et al treated 22 children with primary generalized dystonia for 1 to 3 years with DBS and found that motor subscores improved by 84%, 93%, and 94% at 1, 2, and 3 years, respectively, with equivalent improvements in function.^{10,7} Although most reports of DBS for secondary dystonia have not been encouraging, a recent report of 14 children with dystonic CP who were treated with DBS in a noncontrolled, nonblinded manner reported significant reductions of dystonia on two dystonia scales and improvements in the BFM Dystonia Disability Scale.¹⁰⁸

For children with severe, refractory, secondary or heredo-degenerative dystonia who do not respond to oral medications and for whom ITB and DBS are not available, myotomies, cervical rhizotomies, and selective peripheral denervation may be helpful.¹⁰⁹

Patients with focal upper extremity dystonia are being treated with motor cortical stimulation, in which an epidural electrode strip or grid is implanted over the motor cortex innervating the dystonic region (► Fig. 76.4).^{110–113} The rationale for motor cortical stimulation is similar to that for DBS—interruption of the pathophysiologic cortical–basal ganglia–cortical circuit. There are no published reports of motor cortical stimulation in children. We used it in two young adults with focal secondary dystonia and observed mild improvement in dystonia, but no change in function.

76.3 Athetosis and Chorea

Athetosis is characterized by slow, distal, wormlike, writhing movements of the extremities, often with fanning and hyperextension of the digits. It may be unilateral or bilateral. The term also applies to the writhing perioral movements that garble the speech of individuals with athetoid CP. The pathophysiology of athetosis is unknown. It affects perhaps 10% of individuals with CP (far fewer than before kernicterus could be treated effectively), occurs more often in those born at term, and is more often associated with normal intellect. Athetosis begins during the first 2 years of life in 65% of cases and before the fifth year in 92%.¹¹⁴ It is nonprogressive and becomes associated later in childhood with other CP movement disorders in approximately 45% of cases.¹¹⁵ Athetosis is often confused with dystonia. Some movement disorder specialists consider athetosis to be a form of dystonia, but the two are different. Dystonia responds to ITB well, and athetosis responds only mildly. Choreoathetosis can be graded on a dyskinesia impairment scale.¹¹⁶

The classic pathologic substrate in athetoid CP is status marmoratus of the corpus striatum—which is marbling caused by a

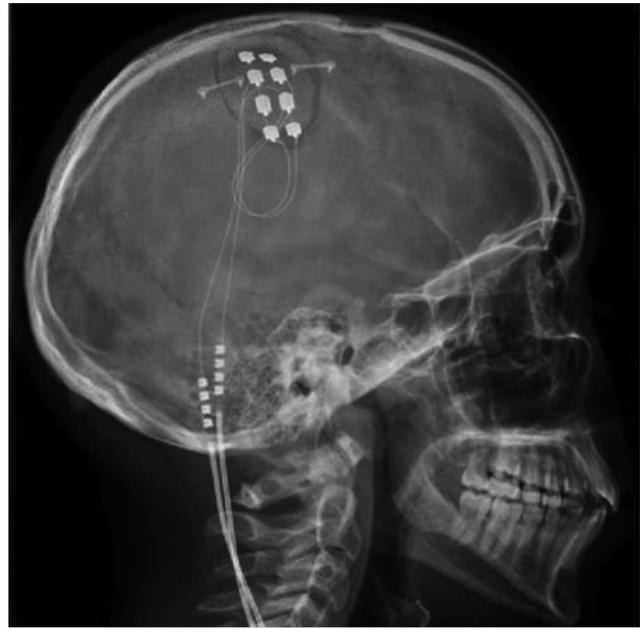

Fig. 76.4 Epidural cortical motor stimulation via a strip electrodes for focal dystonia of an upper extremity.

coarse network of myelinated fibers that disturb the normal radial pattern. Athetosis after kernicterus is typically associated with lesions in the globus pallidus and subthalamic nucleus; athetosis after head injury is more often associated with lesions in the striatum. MR imaging of children with athetoid CP shows no abnormalities in 40%. It shows hyperintense lesions in the ventrolateral thalamus in 60% and in the putamen in 30%.¹¹⁷

Severe athetosis is exceedingly difficult to treat. No oral medications are particularly effective, botulinum toxin injections are unhelpful, ITB helps only mildly, and most case reports of DBS for athetosis indicate little benefit.

Chorea has been described as “a state of excessive, spontaneous movements, irregularly timed, nonrepetitive, abrupt in character” and is characterized by involuntary, rapid, brief, unsustained, dancelike movements.¹¹⁸ Chorea is often worse at rest than during movement. Chorea has been reported to develop in up to 25% of patients with CP, often between 3 to 5 years of age, and is usually associated with an IQ of at least 70.¹¹⁹ Recently, however, the frequency of chorea in CP has appeared to be lower, probably 5 to 10%. Choreiform CP must be distinguished from benign hereditary chorea, which may also commence in early childhood but is not associated with other hallmarks of CP.¹²⁰ Chorea may progress for several years during childhood, perhaps because of the maturing anatomical substrate required for these movements. The pathophysiology of chorea is poorly understood but is thought to involve either destruction or inhibition of the subthalamic nucleus.²

Chorea is treated with tetrabenazine, benzodiazepines, propranolol, and haloperidol. Tetrabenazine, a dopamine receptor blocker, has been reported to be quite effective for chorea.¹²¹ Benzodiazepines, particularly clonazepam, are sometimes effective, although tolerance may develop (► Table 76.5).

In the past 5 years, we have used ITB to treat a few children with severe generalized chorea and observed little improve-

Table 76.5 Oral medications for hyperkinetic movement disorders

Medication	Mechanism of action	Oral doses	Movements treated	Side effects
Trihexyphenidyl (Artane; Lederle Pharmaceuticals, Carolina, NC)	Anticholinergic	2–15 mg divided into 2 doses	Dystonia	Dry mouth, nausea, blurred vision
Diazepam (Valium; Roche, Nutley, NJ)	Benzodiazepine receptor agonist	1–10 mg divided into 2 or 3 doses	Athetosis	Drowsiness, ataxia
Baclofen (Lioresal; Novartis Pharmaceuticals, East Hanover, NJ)	GABA agonist	20–120 mg divided into 2 or 3 doses	Dystonia	Lethargy, nausea, hypotonia
Carbamazepine (Tegretol; Novartis Pharmaceuticals)	Affects sodium channels	15–20 mg/kg/d divided into 2 or 3 doses	Dystonia	Drowsiness, rash, bone marrow suppression
Clonazepam (Klonopin; Genentech, South San Francisco, CA)	Benzodiazepine receptor agonist	0.1–0.2 mg/kg/d divided into 2 or 3 doses	Chorea, athetosis	Behavior problems, blood dyscrasias, tiredness, extrapyramidal reactions
Levodopa/carbidopa (Sinemet; Bristol-Meyers Squibb, New York, NY)	Indirect dopamine receptor agonist	1–2 tablets 2 or 3 times daily	Dystonia	Nausea, chorea
Propranolol (Inderal; Akrimax, Cranford, NJ)	Blocks β -adrenergic receptors	40–120 mg/d divided into 2 or 4 doses	Chorea, tremor	Bradycardia, dizziness, depression, bronchospasm
Haloperidol (Haldol; Janssen Pharmaceuticals, Titusville, NJ)	Dopamine receptor antagonist	0.5–3 mg/d divided into 2 or 3 doses	Chorea	Sedation, extrapyramidal reactions

Abbreviations: GABA, γ -aminobutyric acid.

ment. Radio-frequency lesions have been made in the ventrolateral thalamus and ventroposterior pallidum to treat chorea that is unresponsive to medications. DBS may have a role in the treatment of unilateral choreiform CP, but experience is limited.¹²²

The potential of DBS to help patients with mixed movement disorders, such as combined dystonia and choreoathetosis, was demonstrated in a recent multicenter study of 13 adults with dystonia–choreoathetosis who had only mild abnormalities of the basal ganglia on MR imaging.¹²³ Their BFM Dystonia Scale scores improved from a mean of 44 preoperatively to 35 at 1 year postoperatively. Function, pain, and mental health–related quality of life were significantly improved. Such results suggest trials of DBS in children with similar mixed movement disorders if their MR imaging findings are relatively normal.

Pearls

- IM botulinum toxin injections decrease spasticity in localized muscles and act as a bridge to treat spasticity in children between 3 and 6 years of age, after which patients are old enough for more definitive procedures.
- ITB improves spasticity in the upper and lower extremities and is often associated with improved activities of daily living and improved communication.
- Lumbar dorsal rhizotomies provide permanent relief of spasticity, improve spasticity in both the upper and lower extremities, and often improve gait, with results persisting as long as 20 years.
- Generalized secondary dystonia is frequently misdiagnosed as spasticity, is common in children with CP, and can be treated effectively with ITB.
- DBS is highly effective for primary dystonia, mildly to moderately effective for secondary dystonia, and helpful for some individuals with mixed dystonia–choreoathetosis.

77 Shunt Infections

Dominic N. P. Thompson and John C. Hartley

Hydrocephalus is the most common neurosurgical disorder managed by pediatric neurosurgeons and perhaps the one associated with greatest morbidity. In the United States alone, it has been estimated that there are between 38,200 and 39,900 admissions per year for pediatric hydrocephalus, accounting for more than 400,000 hospital days and costing between 1.4 billion and 2.0 billion dollars.¹ Although in recent years there has been a resurgence of interest in alternative methods of treatment of hydrocephalus, including endoscopic third ventriculotomy and choroid plexus ablation, shunt devices continue to be the mainstay of hydrocephalus treatment. The complications and morbidity associated with the placement and maintenance of ventricular shunts are well documented in the neurosurgical literature, and in virtually all series the problem of shunt infection has been a significant feature. Although infection rates as low as 1.04% have been reported,² rates between 3 and 15% are more representative of neurosurgical practice.^{3–9} Among children with shunt infection, a mortality rate of 10% has been reported¹⁰ furthermore, seizure disorders,¹¹ cognitive impairment, and reduced academic achievement^{10,12} are more common in these children than in those who have not had infection. In addition to the clinical consequences of shunt infection, there is an economic burden, given that it is estimated that the hospital cost of treating a shunt infection is \$50,000, making it the most costly implant-related infection in the United States.¹³

Although neurosurgeons have long recognized the importance of reducing shunt infection rates and numerous preventative strategies have been employed in pursuit of this goal, the strategies are institution-based, variably applied, and frequently unsupported by clinical evidence.¹⁴ Even in more recent series, between 4 and 12% of shunts become infected within 6 months of placement.^{15,16} In this chapter, the etiology of shunt infections is examined, and the contemporary understanding of the microbiology and pathogenesis of shunt infection is reviewed. Surgical management of shunt infection is discussed, and guidelines aimed at preventing or reducing shunt infection and its sequelae are presented.

77.1 Etiology and Pathogenesis

Infection results when a shunt becomes contaminated by an organism capable of establishing growth at the operative site, within the cerebrospinal fluid (CSF) and/or on the shunt hardware itself. Contamination may occur (1) at the time of shunt insertion because of contamination of the shunt tubing, CSF, or exposed wound; (2) through the wound during the early post-operative period before full skin integrity is re-established; or (3) after insertion by direct contamination (e.g., following shunt tap or by contiguous spread of abdominal infection).

An etiologic distinction is made between infections that begin as surgical wound infections enhanced by the presence of a biomaterial (external infections) and those that begin with colonization of the shunt itself (internal infections).¹⁷ From a clinical perspective, infections may be classified according to their location as superficial incisional, deep incisional (below

the fascia, with or without extension to the external part of the shunt), or CSF (infection within the shunt, ventricle, or peritoneum). Unless stated otherwise, we have used the term *shunt infection* to indicate infection of the CSF.

77.2 Causative Bacteria

The majority of shunt infections are caused by staphylococci (gram-positive cocci). Staphylococci are divided into two groups on the basis of their ability to produce the enzyme coagulase and are easily differentiated in the laboratory by the coagulase (or other equivalent) test. *Staphylococcus aureus* produces coagulase and is therefore coagulase-positive. Most staphylococci do not produce coagulase, and these comprise the coagulase-negative staphylococci (CoNS). Where the CoNS have been accurately identified in human infection, *Staphylococcus epidermidis* is the most commonly found species. In almost all reported studies of shunt infection, CoNS are the most common infecting agents, accounting for at least half of cases. *S. aureus* accounts for a further quarter of cases.^{18–23} The remaining quarter of cases are due to gram-positive rods, other gram-positive cocci, and gram-negative rods (► Table 77.1). Propionibacteria are a not uncommon cause of shunt infection; however, the organisms can be difficult to isolate, and prolonged anaerobic culture is recommended.²⁴

The microbiological profile of shunt infections that present a year or more after shunt insertion is different. In these “late” infections, staphylococci are seen less often, and there is a predominance of gram-negative organisms. These infections are less likely to be related to the shunt insertion procedure (hence the lower preponderance of *Staphylococcus* species), and in as many as three-quarters of cases some additional event, such as peritonitis, hematogenous spread, or bowel perforation, can be identified as the precipitating factor.²⁵

77.2.1 Source of Infecting Bacteria

It is clear that the majority of shunt infections are caused by gram-positive pathogens that are typical of the commensal skin flora, and an association has been demonstrated between perioperative skin bacterial density and the risk for shunt

Table 77.1 Organisms responsible for shunt infection

Organism	Shunt infections (%)
Coagulase negative <i>Staphylococcus</i>	60
<i>Staphylococcus aureus</i>	18
Gram positive rods (<i>C. diphtheriae</i> , <i>P. acnes</i>)	10
Other gram positive cocci (<i>Streptococcus</i> , <i>Micrococcus</i> , <i>Enterococcus</i>)	6
Gram negative rods (<i>E.coli</i> , <i>Pseudomonas</i> , <i>Enterobacter</i>)	6

infection.²² Skin preparation (even with alcohol-based agents, which are more effective than aqueous agents) will kill the majority of skin surface organisms. However, some bacteria in the deeper layers of the epidermis and in hair follicles may survive this process, and indeed, in two studies in which wound swabs were taken during shunt operations, positive cultures were obtained in 37% and 58% of cases, respectively.^{26,27} Whether or not the organisms cultured from operative swabs are exclusively from the patient (as opposed to the surgeon or operative environment), and whether it is these specific organisms that will be responsible for subsequent shunt infection, remain controversial.

Shunt contamination may theoretically occur through the deposition of airborne organisms on shunt components or the wound; however, there is little evidence to assess the contribution of this route, and its role is not thought to be significant. With respect to the surgeon as a source of pathogens, in one study cultures from the surgeon's gloves at the end of shunt surgery were positive for skin commensal bacteria in 39% of cases.²² In another study, breach of the surgeon's gloves was identified in one-third of cases, and this was an independent risk factor for shunt infection in that series.²⁸ Although the practices of double gloving, glove changing, and minimal shunt handling during surgery are supported by these findings, the evidence that commensal bacteria from the surgeon are an important source of shunt infection pathogens is weak. The patient's own flora continue to be the most commonly cited source of shunt-infecting pathogens, although again, supporting evidence is far from conclusive. Seven of nine shunt infections studied by Bayston and Lari were due to organisms that had been cultured preoperatively from the patient,²⁷ although whether the typing methods available at that time can be relied upon to establish that these were identical species might be debated. Shapiro et al found that only 20% of shunt infections could be related to cultures from the skin incision,²³ and in a prospective study, Pople et al identified shunt infections in 3 of 30 infants younger than 6 months, although in only one of these were the authors confident that the organism originated in the patient's flora.²² In the authors' experience, intraoperative contamination has been clearly demonstrated; however, we were unable to show a clear association between intraoperative bacterial isolates and the organisms responsible for subsequent shunt infection.²⁶ These apparently disparate findings might be explained by the suggestion that the surgical wound is contaminated by multiple strains of skin bacteria yet only a limited number progress to infection. Furthermore, in the days following surgery, as the commensal flora repopulates, the sutured surgical incision likely remains a potential portal of entry for bacteria.

77.2.2 Bacterial Factors

The mechanisms by which bacteria infect shunts have direct implications not only for our understanding of the treatment of shunt infection but also for the development of preventative strategies. Soon after placement of a shunt, there is a local tissue response that results in the deposition of host proteins over the tubing. Certain bacteria have surface-binding proteins or adhesins capable of binding directly to the shunt surface or to host proteins, thus facilitating bacterial adhesion to the

catheter; this represents the first step toward shunt infection. It is now known that once bacterial adhesion has taken place, genetically driven metabolic changes occur within the bacteria. The bacteria become capable of producing an extracellular "mucoid" material rich in polysaccharides, glycolipids, and glycoproteins commonly referred to as "bacterial slime," although now more properly referred to as polysaccharide intercellular adhesin or exopolymer.²⁹ Colonies of bacterial cells are suspended within this exopolymer, and the resulting amalgam of cells and extracellular material, known as a biofilm, progressively coats the surface of the shunt tubing. The biofilm is a complex microenvironment in which there is an interaction between the infecting organism and the inflammatory host response. Additionally cell to cell signaling between bacterial cells results in expression of genes that further enhance their ability to produce exopolymer.^{29,30} The high failure rate of antibiotic therapy alone as a treatment for shunt infection has been attributed to the effect of the biofilm, which constitutes a physical barrier to the penetration of antibiotics. The reality is likely to be a far more sophisticated developmental strategy on the part of the bacteria. It is now known that early on in the establishment of the biofilm, additional phenotypic changes take place within the bacteria that modify some of the pathways that would previously have been targeted by the antimicrobials, thus further ensuring survival and propagation of the biofilm.³¹ This is important when treatment strategies are considered because organisms in an established biofilm are unlikely to be eradicated by antibiotics alone; hence the need to remove the shunt as part of the shunt infection treatment strategy.

These preliminary stages of shunt infection—initial bacterial adhesion and early proliferation of bacteria within the biofilm—represent potential targets for preventative strategies, and the recent generation of hydrogel-coated and silver- or antibiotic-impregnated shunts has been developed with this in mind.

Interestingly, the introduction of antimicrobial-impregnated shunts may have changed the demographic of shunt infection, with an apparent reduction in the incidence of CoNS shunt infections (► Table 77.2).

S. aureus organisms are additionally more likely to be responsible for incisional infections with or without involvement

Table 77.2 Comparison of organisms responsible for shunt infection before and after the introduction of Bactiseal catheters

Organism	Historical cohort (1993–2003) 1592 shunts Infections = 133 (8.35%)	Bactiseal cohort 2003–2010 499 shunts Infections = 25 (5.10%)
Coagulase negative staphylococci	69	4
<i>Staphylococcus aureus</i>	42	10
Propionibacteria	2	4
Streptococcal/enterococcal sp.	10	5
Gram negative	5	2
Organism not isolated	7	1

Data from Departments of Neurosurgery and Microbiology, Great Ormond Street Hospital for Children, London, UK.

of the adjacent shunt because they produce a range of toxins and enzymes that allow them to survive the host cellular immune response. Therefore, *S. aureus* is more often responsible for those infections that begin with wound-related problems, such as wound breakdown, stitch abscess, and CSF leakage.

77.3 Timing of Shunt Infection

Shunt infection develops at a median time of 3 weeks (interquartile range, 1.5 to 5 weeks) after shunt surgery.³² Approximately 70% of shunt infections present within 2 months of shunt surgery, and 80% have presented by 6 months.³³ This temporal association supports the assertion that shunt infection is essentially a surgical complication that many would argue is potentially avoidable by appropriate attention to surgical technique.² The bacterial pathogenesis of acute shunt infection is discussed above. Shunt infections occurring 1 year or more after surgery are considered late infections and comprise up to 12% of cases.¹⁰ Both the causative bacteria and the underlying mechanism of shunt infection tend to be different. Two mechanisms of late shunt infection are to be considered. In the first mechanism, infection is likely initiated at the time of shunt insertion but is slow to manifest. Particularly indolent shunt infections, such as those caused by *Propionibacterium acnes*, typify this mode of infection. The causative organism may have been inoculated into the peritoneum at the time of surgery yet proliferates slowly, resulting in pseudocyst formation or less frequently ascites.³⁴ The presentation in such cases reflects poor CSF absorption, causing abdominal distension or impaired distal drainage. The second mechanism of late shunt infection is due to a post-insertion event, such as appendicitis, erosion of the catheter into the colon, or abdominal surgery. An underlying cause is present in as many as three-quarters of cases, and although the source may not be immediately evident, an exhaustive search should be pursued. Less obvious candidates include hematogenous spread from distal sites, such as the ear, nose, throat, urinary tract, and lungs.^{25,35} Late infections can occur many years after shunt surgery, and it has been suggested that the risk for such late shunt infection is cumulative over time.²⁵

77.4 Risk Factors for Shunt Infection

Numerous studies have sought to identify risk factors for the development of shunt infection; however, in many single-institution studies, the validity of the findings is compromised by small sample size and additional confounding factors, such as patient selection bias, variations in operative technique, and antibiotic prophylaxis. Inclusion criteria frequently differ between studies; some include only primary insertions, whereas others include revisions, and many studies relate to particular age groups or etiologies of hydrocephalus. Furthermore, some authors report infection rates per procedure rather than per patient, and as a result patient-related risk factors can be easily overlooked. During the following review of risk factors, it is important to take these issues into account because they may shed light on the apparently contradictory findings of some studies.

Pediatric patients with hydrocephalus are an extremely heterogeneous population, and although the following factors are among those that have been repeatedly identified to increase the risk for shunt infection, the risk to an individual patient will commonly reflect a complex interplay of more than one of these elements. Broadly speaking, one can usefully distinguish between risk factors that are intrinsic to the patient (or the patient's underlying condition) and those that are extrinsic.

77.4.1 Intrinsic Factors

Age

Most studies concur that the risk for shunt infection is greater in children than in adults.^{36,37} Even after other variables have been accounted for, young age appears to be an independent risk factor for shunt infection.^{10,32} It is within the infant population that the effect of age is most marked. Kulkarni et al found that premature infants with a gestational age of less than 40 weeks at the time of surgery were at greater risk for shunt infection compared with older infants and children (hazard ratio [HR], 4.72; 95% confidence interval [CI], 1.71 to 13.06).²⁸ In the study of McGirt et al, placement of a ventriculoperitoneal shunt in a premature neonate was associated with an almost fivefold increase in the risk for shunt infection ($p < 0.1$).³⁸ Immunologic immaturity, greater density of the skin bacterial flora, and poor skin quality are among the reasons cited for the greater vulnerability of this group.^{22,39}

Etiology of Hydrocephalus

The intraventricular hemorrhage of prematurity accounts for a significant proportion of cases of pediatric hydrocephalus, and recent studies continue to demonstrate that infection rates and early revision rates are particularly high in this group.^{15,40,41} All shunt-related complications tend to be particularly prevalent in patients with myelomeningocele compared with other etiologies, and shunt infection is no exception. Shunt infection rates as high as 25% are reported even in large centers^{10,42} for this group of patients. Because patients in this group have particularly high rates of shunt revision surgery, the "per patient" risk for shunt infection is also high. This propensity for shunt infection is most likely related to the need for an additional transdural neurosurgical procedure (i.e., closure of the neural tube defect) because the risk for shunt infection tends to decrease in subsequent shunt procedures. Shunt placement before closure of the myelomeningocele, a high level of the myelomeningocele, and a very large size of the ventricles (Evans index > 70) have all been correlated with increased shunt infection rates.^{43,44} When feasible, shunt placement is best deferred until after the myelomeningocele closure, and even then only after a critical appraisal of the need for shunt placement.⁴⁵

Number of Previous Shunt Procedures

Even after controlling for other factors, Simon et al showed that the risk for shunt infection following revision surgery was significantly greater than the risk at the time of initial shunt placement (HR, 3.0; 95% CI, 1.9 to 4.7), and that the risk increased as the number of revisions increased (HR, 6.5; 95% CI, 3.6 to

11.4).³² A prior history of shunt infection also increased the odds of subsequent shunt infection.^{38,46,47} The risk factors for repeated infection are not well understood at present, although the risk is highest in the 6-month period following initial shunt infection, and it is important to distinguish between relapse of an inadequately treated initial infection and a new infection in the same patient.

Other Intrinsic Factors

Other intrinsic factors that have been reported to increase the risk for shunt infection include low birth weight,^{39,48} and comorbidities, such as chronic respiratory disease and sepsis.¹⁸

77.4.2 Extrinsic Factors

Perhaps of more practical relevance are those risk factors that are extrinsic to the patient and diagnosis because these variables, in theory at least, are amenable to modification in an attempt to reduce shunt infection rates.

Cerebrospinal Fluid Leakage and Wound Infection

CSF leakage and wound infection are inextricably linked. CSF leakage through the surgical wound provides a conduit by which bacteria can enter and infect the shunt; moreover, wound infection compromises the integrity of the closure, thus facilitating CSF leakage. Both these surgical complications have consistently been shown to result in increased rates of shunt infection. In the prospective study of risk factors for shunt infection conducted by Kulkarni et al, a postoperative CSF leak was the strongest risk factor (HR, 19.16; 95% CI, 6.96 to 52.91),²⁸ a finding reinforced in a more recent prospective study, in which the incidence of shunt infection was 57.1% in patients with a CSF leak compared with 4.7% in those with no leak.⁴⁹ The importance of meticulous wound closure and diligent wound care in the postoperative period cannot be overemphasized.

Surgeon Experience

The influence of surgical experience on shunt infection rates has been specifically addressed in a number of studies, and most conclude that more experienced surgeons tend to have lower rates of shunt infection.^{18,33,50,51} However, surgical grade does not necessarily correlate with shunt infection rates,⁴⁹ and operative numbers are perhaps a more relevant index. In a study of more than 12,000 shunt procedures performed by 254 surgeons, Cochrane and Kestle observed an infection rate of 7% for surgeons whose shunt procedure numbers were above the 50th percentile and of 9.4% for those whose numbers were below the 50th percentile.⁵¹

Operative Factors

Numerous studies have sought to demonstrate a relationship between various operative factors and the development of shunt infection. These include, among others, an increased risk associated with hair shaving,⁵ intraoperative use of the endoscope,³⁸ excessive numbers of personnel in the operating

room,⁵² position of the case in the operating schedule,² and increased duration of surgery.^{20,52} Many of these studies, however, are retrospective single-institution audits and insufficiently powered; thus, the correlations identified may not be causative. One prospective study did identify repeated exposure of the shunt hardware to breached surgical gloves as a significant risk factor.²⁸

Although the role of airborne pathogens in the etiology of shunt infection remains unproven, the use of high-efficiency particulate air (HEPA) filters in the operating environment has been suggested. This has previously been advocated for orthopedic joint implant procedures, although a recent meta-analysis has questioned its role.⁵³ Currently, there is no evidence available on the effects of unidirectional HEPA-filtered laminar air flow and total-body exhaust suits in shunt insertion surgery.

77.5 Clinical Presentation

Shunt infection is almost always secondary to a surgical intervention. In a retrospective study of almost 1,000 patients with shunts younger than 21 years, factors associated with shunt infection were shunt surgery within the preceding 90 days (adjusted odds ratio [OR], 2.4; 95% CI, 1.3 to 4.4) and presentation with fever (adjusted OR, 8.4; 95% CI, 4.3 to 16.3).⁵⁴ Although shunt infection should always be considered when a child presents unwell or with unexplained symptoms, particularly fever soon after shunt surgery, a full history and clinical examination should be performed in all cases, with the examiner remaining alert to alternative diagnoses, such as upper respiratory tract infection, otitis media, and urinary tract infection (particularly in patients with myelomeningocele). Nonspecific symptoms of headache, vomiting, and lethargy will be present in half of children with shunt infection; thus, there is significant overlap with the symptoms of shunt blockage, and indeed shunt blockage may coexist with shunt infection. Additional clinical features, such as pyrexia and meningism, will increase the index of suspicion of shunt sepsis. Problems of surgical wound healing should be specifically looked for, in particular erythema along the shunt track, wound breakdown, purulent discharge, and CSF leakage, because these are strongly associated with shunt infection.⁴⁹

Less commonly, the presenting symptoms of shunt infection are related to the distal site of drainage. With ventriculoperitoneal shunts, abdominal pain, nausea, and swelling commonly herald a distal shunt infection. This presentation may occur many months after the shunt procedure (which is an exception to the usual temporal association between surgery and infection), and this likely reflects the low pathogenicity of the infecting organisms. Abdominal swelling may be caused either by the formation of loculi of infected CSF within the peritoneum or by the accumulation of infected ascites throughout the peritoneal cavity (► Fig. 77.1a).³⁴

Abdominal ultrasound can usually identify the septa or pseudocyst walls that typify compartmentalized collections of infected CSF and distinguish these from the diffuse free peritoneal fluid of infected ascites. The distinction may have implications for the future options for CSF drainage once the infection has been eradicated. In the case of a loculate infection, simply relocating the peritoneal catheter to a new abdominal site will

Fig. 77.1 (a) Abdominal swelling due to accumulation of infected CSF. (b) Protrusion of distal tubing through the mouth due to erosion of shunt tubing into the upper GI tract. (Courtesy of Dr. A. Leland Albright.) (c) Protrusion of distal tubing through the anus due to migration of distal tubing into the lower GI tract. (Courtesy of Dr. A. Leland Albright.)

usually suffice^{34,55} however, in a patient with a more generalized peritonitis, the absorptive capacity of the peritoneum may have been impaired, and drainage to the atrium or pleural cavity may have to be considered.

Distal infection of a ventriculopleural shunt may also result in impaired CSF absorption—in this instance resulting in shortness of breath, pleuritic chest pain, and empyema. Acute ventriculoatrial shunt infection will present with pyrexia secondary to bacteremia; however, a more specific syndrome of “shunt nephritis” may occur in the context of more chronic ventriculoatrial shunt infection.⁵⁶ This is an immune complex-mediated glomerulonephritis most commonly occurring in association with *Staphylococcus epidermidis* shunt infection; it presents with rash, arthropathy, hematuria, and renal insufficiency and can progress to renal failure if the underlying infection is not adequately treated.

Unusually, the shunt may erode through the skin, bladder, bowel, or oral cavity. In such circumstances, the tubing must be considered contaminated and the patient at high risk for progression to CSF infection, necessitating removal of the shunt and replacement with external ventricular drainage pending the results of CSF analysis (► Fig. 77.1b,c).

77.6 Diagnosis of Shunt Infection

There is no universally agreed-upon definition of shunt-related infection. A distinction should be drawn between superficial wound infections, deep incisional infections (that do not penetrate to the CSF or to the distal compartment of drainage), and “organ space” infections; the latter include classic shunt/CSF infections and isolated peritoneal infections. There is little doubt that incisional infections portend a high risk for subsequent shunt infection, although if identified and treated promptly, they may be adequately managed without recourse to removal of the shunt.

A positive CSF culture is the most definitive diagnostic criterion for shunt infection and whenever possible should be sought before treatment is initiated. However, organisms responsible for shunt infection grow in culture at different rates, and it is worth noting that 25% of CSF cultures from hardware take at least 3 days to become positive.⁵⁷ Culture for at least 10 days has been recommended, and for some organisms extended culture beyond this time will be required. Bacteriologic culture results often need to be interpreted with caution and in conjunction with microbiological advice because culture results are influenced by the method of collection and processing, the availability of repeated sampling, and the prior use of antibiotics. For example, inadequate attention to aseptic technique at the time of sampling can result in false-positives due to contamination with skin commensal bacteria, and false-negatives may result if empiric antibiotic therapy has been commenced before CSF sampling. Additionally, isolation of the infecting agent can prove difficult, particularly in the case of low-grade pathogens such as propionibacteria in an abdominal pseudocyst, which may require prolonged anaerobic culture.

77.6.1 Diagnostic Studies

Blood investigations usually reveal a raised polymorphonuclear leukocyte count,⁵⁴ and the serum level of C-reactive protein (S-CRP) will commonly be raised in the presence of shunt infection.⁵⁸ In one study of children with suspected shunt infection, elevated S-CRP showed 97.1% sensitivity and 73.5% specificity for the presence of shunt infection.⁵⁸ The negative predictive value of S-CRP in this study was 97.3%, so a normal S-CRP level may obviate the need for shunt tap in borderline cases, at least in the initial phase of investigation. S-CRP is also useful as an additional parameter by which to monitor the response to treatment. Blood cultures are usually not positive in ventriculo-

peritoneal shunt infections but can be useful in the evaluation of suspected ventriculoatrial shunt infection.

Where wound discharge or other signs of wound infection are present, microbiological swabs should be taken. Additional investigations, including urinalysis and possibly chest X-ray, should be considered in the search for alternative causes of fever.

Although not necessarily of diagnostic value per se in the context of shunt infection, computed tomography or magnetic resonance imaging of the brain should be performed because shunt obstruction may coexist with shunt infection, and in the event that the shunt has to be replaced with an external ventricular drain, knowledge of the ventricular configuration is essential; it may have changed significantly since the initial shunt placement. In patients with complex shunt histories and multiple revisions, X-rays of the shunt system will not only provide evidence of continuity of the shunt system but also serve as a means of looking for lost or retained shunt tubing, which will require removal along with the shunt to eradicate shunt infection.

Samples of CSF for culture should be obtained not only to establish the diagnosis but also to ascertain microbiological sensitivities in order that appropriate antibiotic therapy can be selected. The percutaneous aspiration of CSF from the shunt system with strict aseptic technique is the most usual method and has a high diagnostic sensitivity compared with lumbar puncture or ventricular tap.⁵⁹ The percutaneous aspiration of shunt reservoirs, although generally safe,⁶⁰ carries some risk for introducing infection and should therefore be performed only when there is reasonable clinical suspicion of shunt infection and after other causes for the clinical presentation have been excluded. In cases of abdominal CSF collections, ultrasound-guided aspiration of CSF can be performed, although in this instance the likelihood of infection is sufficiently high to justify proceeding with externalization of the shunt, which affords the opportunity to aspirate CSF via the distal tubing at the time of surgery.

77.7 Treatment of Shunt Infection

Like with most aspects of this subject, the optimal treatment of shunt infection is controversial, and each of the treatment strategies advocated has its advantages and disadvantages. There are two principal points of contention— firstly, whether intraventricular as well intravenous antibiotics should be used, and secondly, whether or not the shunt should be removed.

77.7.1 Antibiotic Therapy

Intravenous and Intraventricular Antibiotic Therapy

Because CoNS are the most common infecting pathogens, and given the high rates of methicillin resistance of these organisms (60%) in hospital practice, a glycopeptide antibiotic (vancomycin or teicoplanin) is generally considered first-line empiric therapy. However, penetration of the blood–brain barrier by this group of drugs is variable, particularly when there is minimal inflammation, so that intravenous and intrathecal administration is advocated. The dosage should be guided by the regular monitoring of levels to ensure an adequate minimum inhibitory concentration (MIC) while avoiding toxicity. If no intraventricular access is available, intravenous vancomycin

should be supplemented with an additional central nervous system–penetrating drug, such as rifampicin or linezolid. Newer agents, such as linezolid, have good CSF penetration and are a suitable alternative for gram-positive infections, particularly in refractory cases or cases with resistance to first-line antimicrobials.^{61,62} Empiric treatment for a gram-negative infection should be given if one is suspected (if the child is severely systemically unwell, if gram-negative organisms have been seen on CSF examination, or if local epidemiology indicates a high rate of gram-negative infection). An appropriate agent would be a third-generation cephalosporin (if local surveillance data do not show a high rate of extended-spectrum β -lactamase-positive organisms) or a carbapenem, with or without an aminoglycoside. Aminoglycosides also have variable penetration of the blood–brain barrier, so intravenous gentamicin may be supplemented with intrathecal gentamicin when there is a susceptible isolate. Clearly, once an isolate has grown, the antibiotic choice may be modified according to sensitivities.

Factors Influencing the Choice of Antibiotic

The following factors need to be accounted for in choosing an appropriate antibiotic regime:

1. The likely causative organisms. When possible, the CSF should be sampled before antibiotics are started. Broad-spectrum antibiotic cover can then be commenced pending the results of culture and sensitivity tests. The empiric antibiotic policy will need to reflect the commonly seen shunt-infecting organisms in the neurosurgical institution (► Table 77.3). In developing countries, the prevalence of gram-negative shunt infection is such that this might need to be reflected in the choice of empiric therapy—for example, the addition of ceftriaxone, another third-generation cephalosporin, or a carbapenem. (Chloramphenicol can be used if other drugs are not available.)
2. The clinical condition of the child and local signs of sepsis. In an acutely unwell child, broad-spectrum antibiotics may have to be started before CSF sampling to include empiric cover for sepsis appropriate to the age of the child.
3. Colonization with known antimicrobial-resistant microbial flora (e.g., methicillin-resistant *S. aureus* [MRSA], extended-spectrum β -lactamase–producing Enterobacteriaceae).
4. Whether or not the shunt is to be immediately removed.
5. Whether intraventricular access will be available.
6. Local antimicrobial availability.
7. A history of antibiotic allergy.
8. Local patterns of antibiotic resistance.

Pediatric neurosurgical units should develop an agreed-upon treatment policy in conjunction with their microbiologists and infectious disease experts. An example of the treatment policy at our institution is shown in ► Table 77.3.

77.7.2 Surgical Management

With respect to the surgical management of shunt infection, three treatment options have been debated: (1) antibiotics, shunt removal, and placement of an extraventricular drain (EVD); (2) antibiotics, shunt removal, and immediate shunt replacement; and (3) antibiotics only.

Table 77.3 Antibiotic therapy for staphylococcal infection following complete shunt removal with external ventricular drains in situ

Drug	Route of administration	Dose		Therapeutic monitoring	Duration of therapy
Vancomycin	Intraventricular (intrathecal)	Preterm	2 mg daily	CSF levels early each morning; dose only to be given if level < 15 mg/L	Minimum 10 day period following the first negative CSF cultures
		Term–3 months	2.5 mg daily		
		3–6 months	3 mg daily		
		>6 months	5 mg daily		
Vancomycin	Intravenous	See GOS vancomycin guideline and note 6 hour dosing is NOT routinely used alongside intraventricular (intrathecal) vancomycin			

- Initial therapy will be with intraventricular (intrathecal) vancomycin and intravenous vancomycin. This will be subsequently modified according to sensitivity results.
- Directed therapy:
 - *S. epidermidis* and *S. aureus* resistant to flucloxacillin or gentamicin. Continue intravenous and intraventricular vancomycin therapy.
 - *S. epidermidis* or *S. aureus* sensitive to flucloxacillin and gentamicin. Stop vancomycin and change to intraventricular gentamicin plus intravenous gentamicin and cefuroxime.

Antibiotics, Shunt Removal, and Temporary External Ventricular Drainage

This strategy is generally accepted as the current standard of treatment.^{63–65} Only one randomized study has compared the three treatment options, and although the numbers were small, all infections in the removal-plus-EVD group were successfully treated with the shortest hospital stay.⁶⁶

A literature review (not exclusively pediatric) comparing the different modalities of treatment of shunt infection identified 11 studies (224 patients) in which the strategy of shunt removal plus EVD had been used.⁶⁷ The total infection cure rate was 87.7% (95% CI, 83.0 to 91.3), and the mortality rate was 5.7% (95% CI, 3.5 to 9.4). This regime entails at least two surgical procedures and potentially additional surgical incisions because some surgeons like to use separate ventricular sites for the EVD and the definitive shunt. The review concluded that this policy of treatment was superior to the other treatments, assuming that the complication rate of EVD was below 35.8%.

The extirpated infected shunt should be sent for microbiological analysis. It is important that all shunt tubing be removed because retained catheters may harbor bacteria and result in treatment failure (► Fig. 77.2).

The EVD may be placed through the same bur hole, with the opposite side left available for final placement. Prolonged duration of external drainage is a risk factor for secondary infection and drainage may be required for up to 3 weeks in severe gram-negative infections, so that our preference is for a long, tunneled EVD exiting through the chest or abdominal wall. A Rickham reservoir at the bur hole site satisfactorily anchors the drain, preventing migration (which can be a problem in children); it can also be used for the intrathecal instillation of antibiotics, although our usual practice is to inject through a three-way tap incorporated into the externalized drainage system. Management of the EVD requires diligent nursing care, and the system should be accessed only as necessary and with strict aseptic technique. The CSF is sampled to evaluate the response to treatment (white cell count and Gram stain) and to monitor levels of intrathecal antibiotic. Liaison with a microbiologist is essential throughout treatment for determining the optimal antibiotic regimen and duration of therapy.

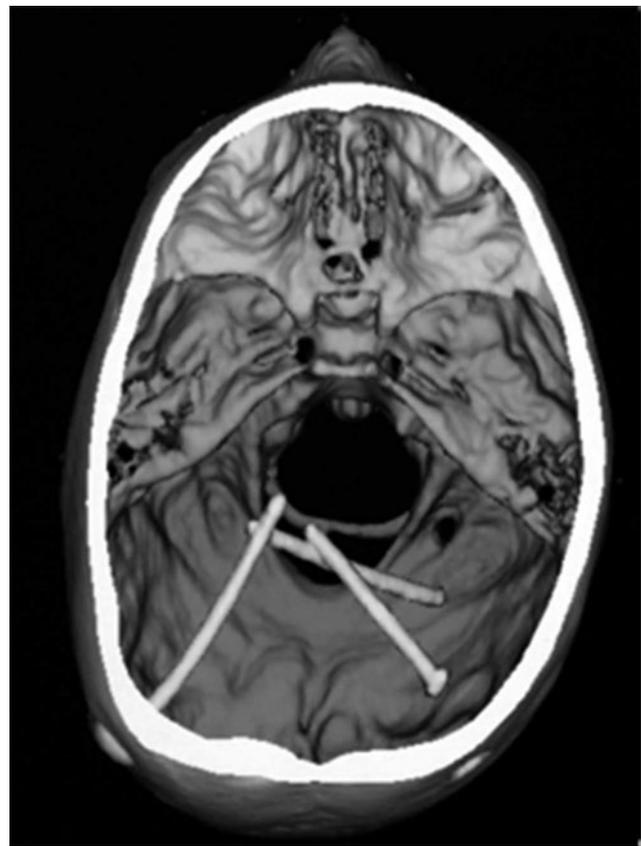

Fig. 77.2 Retained shunt tubing. 3D CT scan showing retained ventricular catheters. Successful treatment of a shunt infection requires the removal of all catheter tubing.

Re-internalization should be delayed until the CSF cultures are sterile and antibiotic therapy is complete. There is no consensus on duration of therapy,⁶⁴ and factors to be considered include the infecting organism, the response to treatment, and the quality of the CSF. CoNS infections usually respond promptly to therapy, whereas *S. aureus* and gram-negative infections may take longer to clear from the CSF. Surgeons are more likely to use external drainage during therapy and a

longer total duration of therapy when dealing with these organisms.^{64,68} A period “off antibiotic therapy” to ensure sterility at the end of treatment increases the risk for reinfection and is generally not warranted. Before re-internalization, elevating or clamping the EVD for up to 12 hours before surgery can make ventricular cannulation easier. Because there is a risk for contamination along the EVD track, many prefer to use a fresh site for the new shunt.

Antibiotics, Shunt Removal, and Immediate Shunt Replacement

The main advantage of this option is that it obviates the need for a second surgical procedure. However, the CSF may not be sterile at the time of insertion, and an elevated CSF cell count may increase the risk for blockage. Intraventricular antibiotic administration in this scenario is more invasive, necessitating ventricular tap or puncture of the shunt reservoir. In the review by Schreffler et al, the cure rate for shunt infection with this regimen was 64.4% (95% CI, 54.2 to 73.6), and the mortality was 11.1% (5% CI, 6.2 to 19.3).⁶⁷ This strategy is reported to have a better outcome with low-virulence, slow-growing organisms such as *P. acnes*.⁶⁹

Antibiotics Alone

This option can be considered only when the shunt remains functional. It has the advantages of avoiding multiple surgical interventions, reducing hospital stays, and lowering treatment costs. In a review of the literature, the cure rate for antibiotics alone was 33.5% (95% CI, 27.7 to 39.4), and the overall mortality was 20.4% (95% CI, 15.7 to 26.1).⁶⁷ Given the propensity of the most commonly implicated organisms to form a biofilm, this high failure rate is perhaps unsurprising; however, Brown et al argued that the failure rate associated with this conservative regime was due to suboptimal antibiotic therapy. With a combination of oral or intravenous rifampicin and intrathecal vancomycin (via a separate subcutaneous reservoir), they reported an 84% cure rate.⁷⁰ Interestingly, their regime was more effective in CoNS infections than *S. aureus* infections.

Experimental data have recently been published to support the potential use of linezolid alone, without shunt removal, and this may be an option in some cases.⁷¹

There are special circumstances in which the occurrence of a central nervous system infection in a child with a shunt does not mandate removal of the shunt. These include cases of meningitis due to *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis* and of tuberculous meningitis in which appropriate medical therapy alone will usually suffice.^{72,73}

The development of a non-shunt-related abdominal or pelvic infection (e.g., appendicitis) has the potential to cause ascending infection and ventriculitis; however, there is no consensus regarding the optimal management of the shunt in this circumstance. In cases of appendicitis, the traditional view has been to recommend externalization of the shunt pending appendectomy and comprehensive treatment of the underlying infection^{74–76} however, more recent studies suggest that leaving the shunt in situ is a safe option so long as the underlying

infection is aggressively treated.^{77,78} In the absence of a clear evidence base, it seems appropriate to suggest that cases be managed on an individualized basis. If the shunt is left in situ, it is essential that the patient's condition be carefully monitored until the septic episode has resolved. The potential for distal shunt malfunction as well as ascending infection must be kept in mind.

Treating Gram-Negative Infection

Gram-negative infections, most commonly with *Pseudomonas aeruginosa* or Enterobacteriaceae (e.g., *Escherichia coli*), are especially serious infections in children, with high morbidity and mortality rates. Antibiotic resistance is increasingly common, the CSF is slow to sterilize, and relapse may occur. Infection should be managed in conjunction with the infectious disease and microbiology service, and although there is no consensus, we advise a minimum of 3 weeks of intravenous therapy, with additional intraventricular aminoglycoside before sensitivities are available and at least until the CSF is culture-negative. The duration of intraventricular therapy is managed on an individual basis. Failure to clear infection may result from underdosing (it is important to ensure that all cephalosporins or carbapenems be given at full “meningitis” dose), abscess formation or loculation, or infection of the EVD. Further surgical management may be necessary, including change of the EVD, during treatment.

77.7.3 Outcome

Despite the apparent efficacy of first-line therapy for shunt infection, repeated infections do occur, representing either a relapse of infection with the original organism due to treatment failure or reinfection with a new organism following shunt replacement. This remains an issue and may be overlooked in studies with inadequate follow-up. Repeated infection rates of 19.6% and 26% have been reported in two North American studies.^{46,47} A distinction should be drawn between treatment failures and reinfections. In the study by Kestle, two-thirds of the repeated infections were with the same organism, suggesting a failure of primary treatment (relapse).⁴⁷ No consistent risk factors have as yet been identified to explain the high rate of repeated infections.

An 10-year audit of the outcome of treatment according to the strategy described for our own institution showed that of 105 shunt infections, 2 were relapse infections (each a deep incisional and CSF infection with *S. aureus*). There was no relapse of an original CoNS infection, but reinfection occurred at a rate identical to the prevailing shunt infection rate at the time of the audit (unpublished data).

77.8 Prevention

77.8.1 Antibiotic Prophylaxis

Because shunt infections frequently arise from bacterial contamination at the time of insertion and are not eliminated by the usual host defense mechanisms, a logical prevention

strategy is the administration of prophylactic antimicrobials. These may be given systemically or locally; local administration may be by direct instillation or by incorporation into implanted materials.

A number of randomized controlled clinical trials have sought to demonstrate the efficacy of systemic antibiotic prophylaxis in shunt surgery, unfortunately with variable conclusions. Because most centers have shunt infection rates of 10% or less, single-institution studies are often insufficiently powered to reach a significant conclusion. It has been calculated that for a study to have an 80% chance of detecting a decrease in the infection rate from 10 to 8.4%, a sample size of more than 8,000 patients is required.⁷⁹ Meta-analysis seeks to overcome the problem of sample size by aggregating the results of multiple smaller studies. Two such analyses have been performed, both finding in favor of the use of prophylaxis.^{79,80} Haines and Walters examined the results of 9 randomized studies and found that the combined infection rates for 527 controls and 516 treated patients were 13% and 7%, respectively. This apparent benefit of prophylaxis was, however, related to the baseline infection rate and was lost if the baseline rate was less than 5%.⁷⁹ The use of intravenous antibiotic prophylaxis for shunt surgery is now almost ubiquitous among neurosurgeons; however, significant variation in practice remains regarding the choice of antibiotic and duration of prophylaxis.¹⁴ Additional measures, such as soaking the shunt in antibiotic solution or administering antibiotic intraventricularly as well as intravenously, are commonplace but have not been demonstrated to provide additional benefit.

Surgeons should be encouraged to engage with microbiologists in their institutions to agree on the details of prophylaxis. Antibiotics should be administered at the time of induction of anesthesia, and the duration of prophylaxis should not exceed 24 hours.

77.8.2 Antibacterial Shunt Technology

Modifying shunt catheters to make them less susceptible to bacterial adhesion and to deliver antimicrobials locally, thereby reducing the chance for shunt infection, has been the source of much research during the past two decades. Broadly speaking, these modifications involve the incorporation of one or more antimicrobial agents into the catheter, either by *coating* the catheter (hydrogel, heparin, or silver) or by *impregnating* antibiotics into the biomaterial during the manufacturing process.²⁹ It is important that the antimicrobial effect of these catheters persist well into the postoperative period if shunt infection is to be prevented. In many cases, *in vitro* results have been encouraging; however, because of the effects of CSF flow, protein deposition, and other factors, efficacy may be compromised in the *in vivo* situation.

Antibiotic-Impregnated Shunts

More than 20 years ago, Bayston demonstrated that the antibiotics clindamycin and rifampicin could be incorporated into Silastic (Dow Corning, Midland, MI) shunt tubing, and an

antibiotic-impregnated shunt (Bactiseal; Codman & Shurtleff, Raynham, MA) has been commercially available since 2002. A number of advantages have been cited. The antibiotic combination is effective against the most common gram-positive shunt-infecting organisms; slow elution from all surfaces of the catheter reduces the potential for bacterial colonization, not only on the external surface of the shunt but also within the lumen; and antibiotic-impregnated shunts continue effective antistaphylococcal activity well into the postoperative period. *In vitro* studies have demonstrated effective protection against a range of *S. aureus* organisms and CoNS for between 42 and 56 days,⁸¹ and *in vivo* studies of explanted shunts suggest that the duration of activity may be substantially longer⁸² (► Fig. 77.3).

A number of attempts have been made to evaluate the effectiveness and economic impact of antibiotic-impregnated shunts. Most of the information is from retrospective studies, and although most indicate a favorable reduction in the shunt infection rate,⁸³ this is not universally the case; as with many shunt infection studies, interpretation of the data is not infrequently constrained by methodologic flaws, including small sample size and inconsistent definitions of shunt infection. Two meta-analyses have been undertaken, both including data from adult and pediatric practice. Both conclude that antibiotic-impregnated shunts are associated with a significant reduction in shunt infection compared with non-antibiotic-impregnated shunts.^{83,84} Klimo et al concluded that the risk for developing a shunt infection with a standard shunt was 2.18 times greater than that with an antibiotic-impregnated shunt. When analyzing the pediatric data separately, Parker et al found a shunt infection rate of 5.0% for antibiotic-impregnated shunts compared with 11.2% for non-antibiotic-impregnated shunts ($p < 0.0001$).⁸⁴ Our own experience concurs with this finding; we experienced a shunt infection rate of 5.1% while using antibiotic-impregnated shunts, compared with 8.35% in our historical control. Interestingly, in the historical series, CoNS infections comprised 51.9% of the infections, compared with 16% in the antibiotic-impregnated shunt group. Larger prospective series will be needed to ascertain whether the microbiological profile of shunt infections will be altered by the more widespread use of antibiotic-impregnated shunts. Although there had been concerns that the use of antibiotic-impregnated shunts might promote the emergence of drug-resistant bacteria, currently there are no reliable data to support this assertion.

The cost of antibiotic-impregnated shunts is greater than that of conventional shunts; however, when institutions have an infection rate of greater than 5%, the savings achieved by avoiding the costs of treating shunt infections make antibiotic-impregnated shunts cost-effective.^{83,85} Both meta-analyses acknowledge the limitations of these conclusions and point to the need for a randomized control clinical trial. The BASICS trial, a national, randomized trial of antibiotic-impregnated, silver-impregnated, and standard silicone shunts, opened in the UK in 2013.

Silver-Impregnated Catheters

Silver has a broad antimicrobial spectrum, and this property has been put to use in urinary and vascular catheters with some

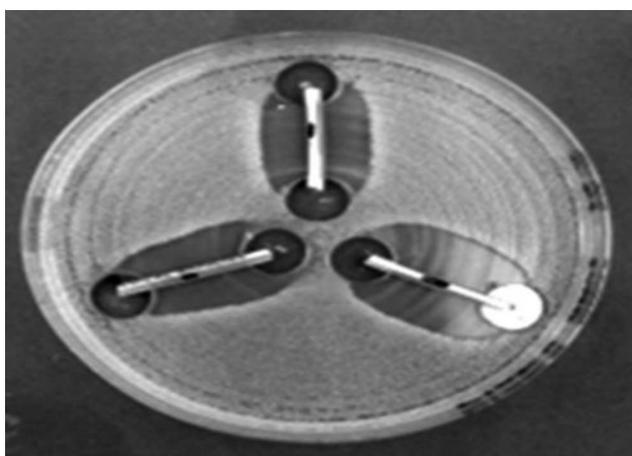

Fig. 77.3 In vitro study demonstrating zones of inhibition of bacterial growth around antibiotic impregnated shunt tubing. (Courtesy of R. Bayston.)

effect. Silver has been incorporated into shunt catheter tubing and is now commercially available (Silverline; Spiegelberg, Hamburg, Germany). Although silver-impregnated tubing is licensed for incorporation into shunt systems, most of the current data pertain to EVD use, in which clinical studies have suggested a statistically significant reduction in CSF colonization compared with controls.^{86,87} Licensing data demonstrate in vitro antimicrobial activity, although an in vitro test model that used inocula much higher than are likely to be encountered in vivo demonstrated that silver catheters were unable to eradicate MRSA or *E. coli* and had limited activity against *S. epidermidis*.⁸⁸ However, a recent randomized trial of EVDs also demonstrated that silver-impregnated tubing produced a highly statistically significant reduction in infection from 21.4% in the control group to 12.3% in the silver catheter group.⁸⁹ There are currently insufficient data to evaluate the efficacy of silver catheters in shunt (rather than EVD) systems.

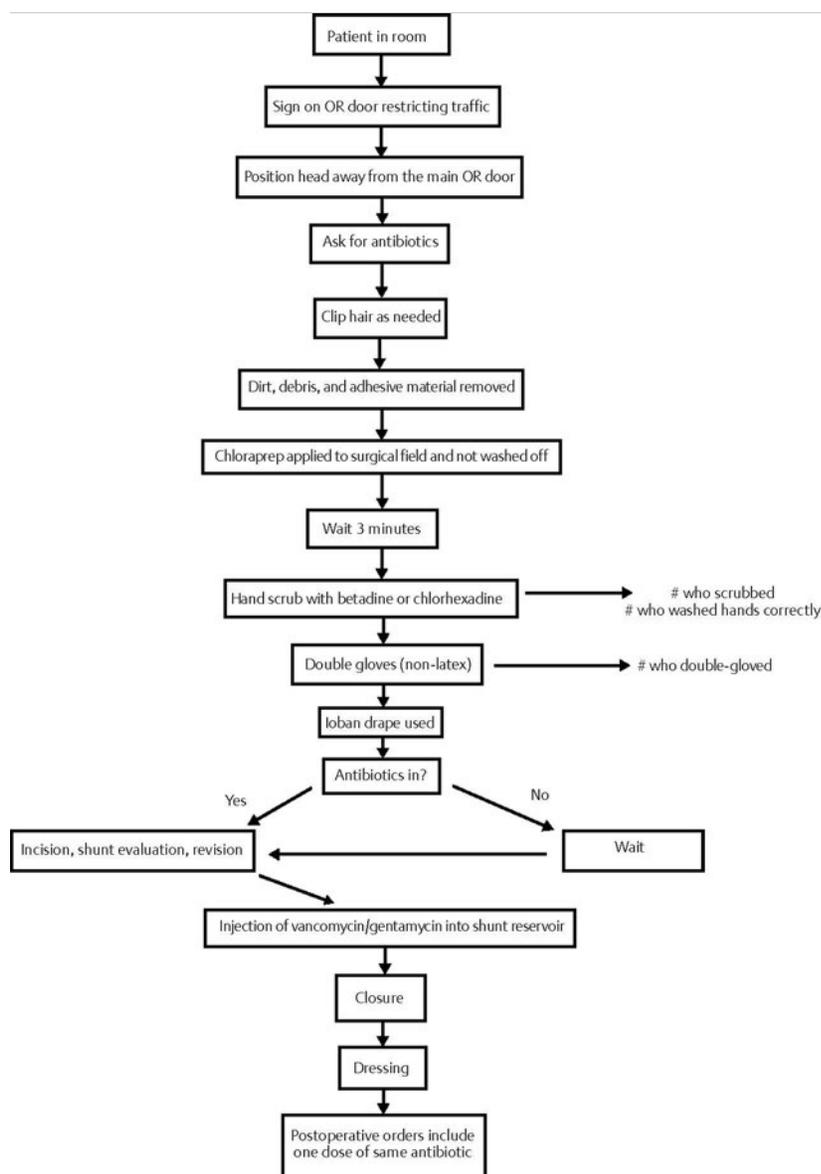

Fig. 77.4 Shunt insertion protocol developed by Hydrocephalus Clinical Research Network.¹¹

Hydrogel-Coated Catheters

In these catheters, a hydrophilic polymer (BioGlide; Medtronic, Minneapolis, MN) is used to coat the catheter surface. Before insertion, the tubing is soaked in water; the polymer swells and thus creates a hydrophilic surface that will impair bacterial adherence. It has been proposed that the addition of antibiotics, which can be absorbed into the polymer, to the soaking solution will confer some further antibacterial activity following insertion. In vitro studies have confirmed reduced bacterial adhesion on hydrogel-coated catheters; however, soaking the catheters in an antibiotic solution failed to prevent bacterial colonization.⁹⁰ In clinical studies of hydrogel catheters, the results have thus far been disappointing. EVD infection rates were not reduced by hydrogel-coated catheters.⁹¹ Few studies have examined hydrogel-coated shunt systems; however, in a recent large study by the Hydrocephalus Clinical Research Network, regression analysis revealed that the use of BioGlide shunts was associated with an increase in the shunt infection rate.⁶⁵

77.8.3 Protocols for Shunt Insertion

Twenty years ago, Choux et al demonstrated that if relatively modest changes to the pre-, intra-, and postoperative management of children undergoing shunt surgery were made and incorporated into a protocol, the goal of a zero rate shunt infection could be achieved.² The importance of surgical training and experience, in addition to strict adherence to a no-touch technique, careful tissue handling, and careful wound closure, in reducing shunt infection rates cannot be overemphasized; however, infection rates that differ between surgeons and centers suggest an ongoing need for unified shunt protocols.¹⁵ It may not be possible for all elements of a protocol to be supported by level 1 evidence; however, as demonstrated by the Hydrocephalus Clinical Research Network, the introduction of a consistent, reproducible, and carefully audited protocol for shunt placement can significantly reduce shunt infection rates (► Fig. 77.4).⁶⁵ When applied across large clinical networks, such a protocol establishes a baseline from which it becomes feasible to begin to evaluate critically and in a statistically more meaningful way not only the causative factors for infection but also the results of interventions designed to reduce infection rates still further.

Given the economic burden and the clinical consequences of shunt infection, it is clear that it is imperative for all shunt surgeons to critically evaluate their own practices and engage in local multidisciplinary surveillance and data collection.⁹² Local practice can be scrutinized and clusters of shunt infection can be identified early, permitting the immediate investigation of causative factors. Only through such transparency and reflection will the morbidity of shunt surgery be reduced.

Pearls

- The majority of shunt infections are caused by commensal skin organisms, the most prevalent being *S. epidermidis*.
- Shunt infections are a complication of surgery; over two thirds of shunt infections are diagnosed within two months of surgery. The majority of shunt infections should be considered a failure of surgical technique.
- Wound-related complications, particularly wound infection or CSF leakage, are the strongest risk factors for shunt infection.
- In cases of suspected shunt infection, CSF sampling should be performed prior to commencement of antibiotic therapy and only after other sources of fever or infection have been excluded.
- Shunt removal, followed by temporary external CSF drainage combined with selective antibiotic therapy, is the most effective strategy for treatment of shunt infection.
- Preliminary studies indicate that antibiotic impregnated shunts reduce shunt infection rates, though randomized clinical trials are required to validate this observation.
- The introduction of shunt insertion protocols has been shown to reduce shunt infection rates. Prospective audit of shunt infection is recommended in order to monitor shunt infection rates and to identify clusters of shunt infection that might require more detailed analysis.

78 Cranial Epidural Abscess and Subdural Empyema

Christine L. Hammer and Joseph H. Piatt Jr.

Epidural abscess and subdural empyema are central nervous system infections that arise as infrequent complications of neurosurgical procedures, open trauma, and common infectious processes, such as sinusitis or meningitis. Until penicillin became widely available in the 1940s, mortality from these infections approached 100%. Contemporary reports now cite mortality rates for subdural empyema in the neighborhood of 10%, and mortality from epidural abscess is exceptionally low.¹⁻⁶ Despite the efficacy of modern antibiotic therapy, timely neurosurgical interventions continue to play an important role in the microbiological diagnosis and control of intracranial hypertension. The coordinated multidisciplinary management of these very sick children yields gratifying clinical recoveries in the great majority of cases.

Epidural abscess, also known as extradural abscess or extradural empyema, is a collection of pus between the dura mater and overlying bone. Subdural empyema is suppuration between the cranial dura and arachnoid membranes. Alternative terms include *subdural abscess*, *purulent pachymeningitis*, *intradural abscess*, and *intrameningeal abscess*.^{7,8} Collectively, epidural abscess and subdural empyema are described in this chapter as *extracerebral suppuration*. The term *intracranial suppuration* may be used to encompass brain abscess as well as epidural abscess and subdural empyema. The term *empyema* connotes pus within a preexisting anatomical space, whereas the term *abscess* describes a collection of pus in the parenchyma of a tissue or an organ. *Empyema* might therefore be an appropriate term for epidural infection as well, but this chapter conforms to the customary usage, which emphasizes the common focality of epidural pus versus the typically diffuse distribution of subdural pus. This distinction also serves to emphasize the relative benignity of infection limited to the epidural space, as will be seen.^{6,7,9}

78.1 Epidemiology

Little is known about the incidence of extracerebral suppuration in childhood. A population-based study drawing on administrative data sets in the United States estimated the annual incidence of hospital admission for intracranial suppuration, including brain abscess associated with sinusitis or otitis, to be between 3 and 4 per million children per year, but this study did not encompass posttraumatic or postsurgical cases or cases of subdural empyema complicating infantile meningitis.⁶ The largest case series of extracerebral suppuration have been reported out of Africa and southern Asia,^{1,2,10-23} but whether these impressive clinical experiences reflect a greater burden of disease or referral to a more limited number of neurosurgical centers from wider geographic regions is impossible to determine. The relative frequencies of epidural abscess and subdural empyema have not been studied in epidemiologic terms, but case series that include both entities tend to cite comparable numbers of each.^{3,8,9,11,24-28} Exceptions are several large case series from Africa that show a marked predominance of subdural empyema.^{2,13,22} Mixed epidural and subdural infections and

associated brain abscesses are not uncommon.^{3,11,27,29-31} Empyema associated with infantile meningitis is exclusively subdural. The etiology of the infection determines the typical age at presentation. Subdural empyema complicating meningitis is a phenomenon of infancy and early childhood.⁸ The incidence of intracranial suppuration complicating sinus and ear disease peaks in mid adolescence.^{2,6,11,13,22,32-34} Regardless of the etiology, a male predominance has been observed consistently at a rate of roughly 2:1.

The dominant etiology of epidural abscess and subdural empyema in childhood is extension from head and neck infection. The facial sinuses, middle ear, and mastoid sinus are the most common primary sites. Subdural empyema complicating dental infection has been reported, but in distinction to its prominent role in the etiology of brain abscess, it accounts for a negligible fraction of cases of extracerebral intracranial suppuration.^{2,35,36} In infancy and early childhood, subdural empyema is seen most commonly as a complication of meningitis.^{8,11,32,37} The following discussion proceeds along these etiologic lines. Posttraumatic and postsurgical infections are fortunately infrequent and are necessarily contingent on preceding trauma or surgery. They are considered only very briefly.

78.2 Sinusitis and Ear Disease

78.2.1 Incidence

Sinusitis and ear disease are very common in childhood, but the incidence of these conditions is poorly defined. The clinical diagnosis is imprecise, and many cases escape medical attention altogether.^{5,28,38} Outpatient management is the rule, and only a small but unknown fraction of patients are admitted to a hospital for parenteral antibiotics. Among 649 patients of all ages hospitalized for sinusitis, Clayman et al recorded intracranial complications, including brain abscess and meningitis as well as extracerebral abscess, in 24 (3.7%).³⁸ Analysis of the 2009 Kids' Inpatient Database (KID) disclosed an estimated 10,906 nationwide admissions with a primary diagnosis of sinusitis, otitis, or mastoiditis. That year, there were an estimated 443 admissions for intracranial suppuration of all types associated with sinusitis or ear disease, for a rate of 4.1% (J.H.P., unpublished data). Thus, the incidence of extracerebral suppuration complicating sinusitis or ear disease can be taken to be less than 1/25th the incidence of hospitalization for these conditions and to be a very tiny fraction of the overall incidence. The miniscule incidence of intracranial suppurative complications of sinusitis has frustrated efforts to prevent them.

78.2.2 Mechanism

Extracerebral suppuration is usually associated with sinusitis involving the frontal or ethmoid sinuses.^{7,39} The next most commonly involved sinus is the mastoid.⁴⁰

Speculation about the mechanisms of spread of infection from the sinuses to the epidural and subdural spaces has been

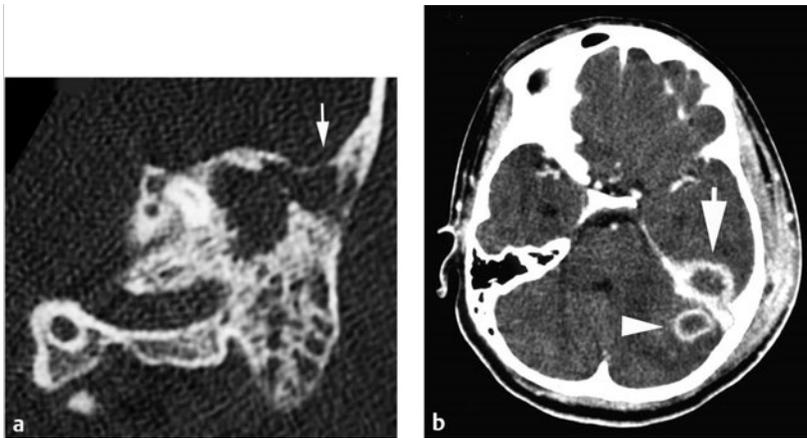

Fig. 78.1 (a) Computed tomographic (CT) scan of the temporal bone of a child with otitis and mastoiditis shows opacification of the antrum and mastoid cells with erosion of the tegmen tympani (white arrow). (b) CT scan of the brain with enhancement in the same patient demonstrates a small abscess in the left cerebellar hemisphere (white arrowhead) and an extracerebral abscess on the floor of the middle fossa (white arrow). At surgery, the middle fossa collection proved to be epidural. (Courtesy of Drs. Joseph Piatt, Jennifer Smith, and Eric Faerber.)

based on gross observations at surgery and at autopsy. Seldom are macroscopic defects observed in the posterior wall of the frontal sinus or the roof of the ethmoid sinus, but in the setting of chronic otitis and mastoiditis, destruction of the roof of the middle ear, the tegmen tympani, can be seen in association with epidural pus on the floor of the middle fossa (► Fig. 78.1a, b). The perforations of the cribriform plate have been mentioned as possible portals for entry of infection, but they are likely more relevant to the pathogenesis of meningitis than of extracerebral suppuration. In the absence of an osseous defect, infection is commonly believed to spread by septic thrombophlebitis of the transosseous venous channels. Spread through the dura may occur on a similar basis. At autopsy, frank necrosis of the dura has been observed adjacent to an infected sinus, accounting for some instances of the breach of what is usually a very stout barrier to the spread of infection.⁷ Septic thrombosis of cortical bridging veins and adjacent dural venous sinuses is more likely a complication of advanced subdural empyema than a mechanistic cause.

78.2.3 Predisposing Factors

Male sex, black race, and age in the early teens seem to impart a vulnerability to intracranial suppurative complications of sinusitis and ear disease. The developmental, anatomical, and physiologic mechanisms underlying these associations have been the subject of speculation, but they are unknown.^{6,26} Factors that contribute to the development of sinusitis necessarily make indirect contributions to the incidence of its complications. Many studies have described a seasonal pattern that seems dependent on geography. In central Europe, cases of complicated sinusitis peak in the month of March,⁴⁰ and reports from Africa and India find most cases of subdural empyema in their summer months.^{4,10,12} In the United States, winter is the dominant season for sinogenic intracranial suppuration,³⁰ but no seasonal pattern is apparent for otogenic cases.⁶ In view of the anatomical, physiologic, and immunologic continuity of the sinobronchial tree, there has been much discussion of the association of sinusitis with allergy and asthma. A large cohort study in the United States identified a strong association of asthma with sinogenic intracranial suppuration. This association did not hold for ear disease.⁶ The linkage between sinogenic intracranial suppuration and asthma raises questions about the relevance of environmen-

tal factors like air quality.⁴¹ Over the first decade of this century, there has been no clear trend in the incidence of sinogenic intracranial suppuration.⁶ Analysis of the 2009 KID shows that patients admitted with a primary diagnosis of sinusitis, otitis, or mastoiditis came from ZIP codes where the median home income was lower than those for other admissions, but this association was not evident for intracranial suppuration complicating sinusitis and ear disease (J. H. P., unpublished data). Adame and colleagues have discussed a possible linkage of sinogenic empyema with diabetes, another prevalent and chronic condition with social and environmental associations.⁴² Geographic and socioeconomic correlations deserve further study.

78.2.4 Clinical Presentation

The initial clinical presentation of epidural abscess complicating sinusitis or ear disease is indistinguishable from the symptoms and signs caused by the primary infection: headache, fever, sinus pain or tenderness, purulent rhinorrhea or otorrhea, and conductive hearing loss. Only later in the course of the illness, if the epidural collection attains sufficient volume to cause mass effect or if complicating subdural suppuration or cerebral abscess develops, can papilledema, focal neurologic deficits, depressed responsiveness, and seizures appear. A special case is the distinctive clinical syndrome of Pott's puffy tumor (► Fig. 78.2). Named after Sir Percivall Pott, an English surgeon who described this phenomenon in 1760, the puffiness reflects subperiosteal pus and osteomyelitis of the frontal bone complicating frontal sinusitis. It is reliably associated with at least some degree of epidural suppuration, and in more advanced cases, subdural empyema or cerebral abscess may be present as well. Pott's puffy tumor has been described as a historical curiosity,⁴³ but it is certainly a feature of contemporary practice.^{11,25,27,42,44–48} Osteomyelitis of the frontal bone raises particular issues for treatment that are discussed below.

Subdural empyema complicating sinusitis or ear disease may be impossible to distinguish from meningitis in its initial clinical manifestations; fever, headache, lethargy, and meningismus are common. The development of focal neurologic deficits and seizures directs attention to the correct diagnosis. Before the current era of computed brain imaging, the clinical triad of fever, seizures, and hemiplegia was viewed as pathognomonic for subdural empyema.

Fig. 78.2 Computed tomographic scan with enhancement of the brain in a case of frontal sinusitis with Pott puffy tumor. The scan shows a large subperiosteal abscess (asterisk) and a smaller epidural abscess (arrow). (Courtesy of Drs. Joseph Piatt, Jennifer Smith, and Eric Faerber.)

78.2.5 Microbiology

Streptococcus and *Staphylococcus* species are the most common isolates.^{4,5,9–11,13,27–31,33,49–53} Most frequently mentioned by genus and species is *Streptococcus milleri*. In contemporary parlance, this term refers to a group of α -hemolytic viridans streptococci—*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*, the so-called *Streptococcus milleri* group (SMG).⁵⁴ SMG organisms are typically pyogenic and tend to be found in association with the gastrointestinal tract, oropharynx, facial sinuses, and teeth. Gram-negative organisms, particularly *Pseudomonas*, are prevalent in cases of otogenic suppuration associated with cholesteatoma.^{55,56} The meticulous handling of specimens discloses substantial rates of anaerobic and polymicrobial infection that must be considered in treatment planning.^{29,53,57–59} In geographic regions where it is prevalent, tuberculosis is a possibility as well.⁶⁰ Intracranial pus yields positive cultures in upward of 65% of cases.^{2,4,5,10,11,13,16,25,27,29,31,33,34,44,50–53,57,61}

Once the existence of sinogenic or otogenic intracranial suppuration has been recognized, lumbar puncture is no longer indicated. As a diagnostic priority, lumbar puncture is superseded by the sampling of pus from the intracranial collections and the sinuses, and in the presence of intracranial mass effect, lumbar puncture may be contraindicated because of the risk for herniation, a complication mentioned frequently in the older literature.^{13,62,63} Culture-positive cerebrospinal fluid (CSF) has been reported in fewer than half of cases of subdural empyema, and in many reports the culture yield is nil.^{5,13,20,42,51,52,62,64–66} The

CSF formula generally conforms to a parameningeal pattern: a neutrophil-predominant pleocytosis with elevated protein and normal glucose.⁶² The CSF findings associated with epidural abscess have received little attention in the literature.²

Blood cultures are obtained routinely and have been reported to be positive in up to 40% of cases.^{5,10,27,50,52} Other laboratory studies, such as the white blood cell count, erythrocyte sedimentation rate, and C-reactive protein level, are unlikely to impact the diagnostic process, but they may be useful to follow the response to treatment. Reports from two centers have noted that although the C-reactive protein level and erythrocyte sedimentation rate are consistently elevated in patients with sinusitis, these markers are much higher in cases complicated by intracranial suppuration.^{27,42}

78.2.6 Imaging

The decision for brain imaging in the patient with suspected intracranial suppuration seldom lies in the hands of the neurosurgeon, but for monitoring the patient's response to treatment, computed tomography (CT) and magnetic resonance (MR) imaging both have strengths and weaknesses that must be considered.

CT is adequate for most neurosurgical purposes. Extracerebral suppuration generally exhibits low density compared with brain (► Fig. 78.3a). Epidural abscess has the expected biconcave morphology (► Fig. 78.5), and subdural empyema spreads more widely and conforms more closely to the contour of the adjacent brain. With the administration of contrast, there is pachy- and leptomeningeal enhancement surrounding the collection (► Fig. 78.3b). An advantage of CT is precise demonstration of the osseous anatomy and pathology in the calvaria and in the facial sinuses and temporal bones. The prevailing navigation systems for endoscopic sinus surgery, often undertaken by colleagues in otolaryngology concurrently with the neurosurgical drainage of intracranial pus, rely on CT data sets. A disadvantage of CT is the artifactual image distortion that occurs at the interface between high-density bone and adjacent low-density soft tissue, so-called beam hardening. Unfortunately, in this clinical context the regions of the cranial cavity immediately adjacent to the skull are of paramount interest—the epidural and subdural spaces and the dural venous sinuses. Another potential weakness of axial CT relates to the evaluation of lesions at the vertex of the cranial cavity, a not uncommon site for epidural abscess.⁸ Sagittal and coronal reconstructions obviate this problem. Without a doubt, CT has poorer image clarity and lower sensitivity than MR imaging. When CT is employed as an initial diagnostic test, the occurrence of false-negative results of noncontrast CT must be born in mind,^{27,42,67–69} and if intracranial infection is suspected prospectively, contrast must be administered.⁷⁰

MR imaging offers much more anatomical and physiologic information than CT, but whether this information justifies the additional logistical complexity and commitment of time requires consideration on a case-by-case basis. Epidural and subdural pus are generally low-intensity on T1-weighted and fluid-attenuated inversion recovery (FLAIR) sequences and high- or mixed-intensity on T2-weighted sequences.⁷¹ Enhancement patterns are similar to those on CT (► Fig. 78.3c). Diffusion-weighted imaging (DWI) detects ischemic injury in brain

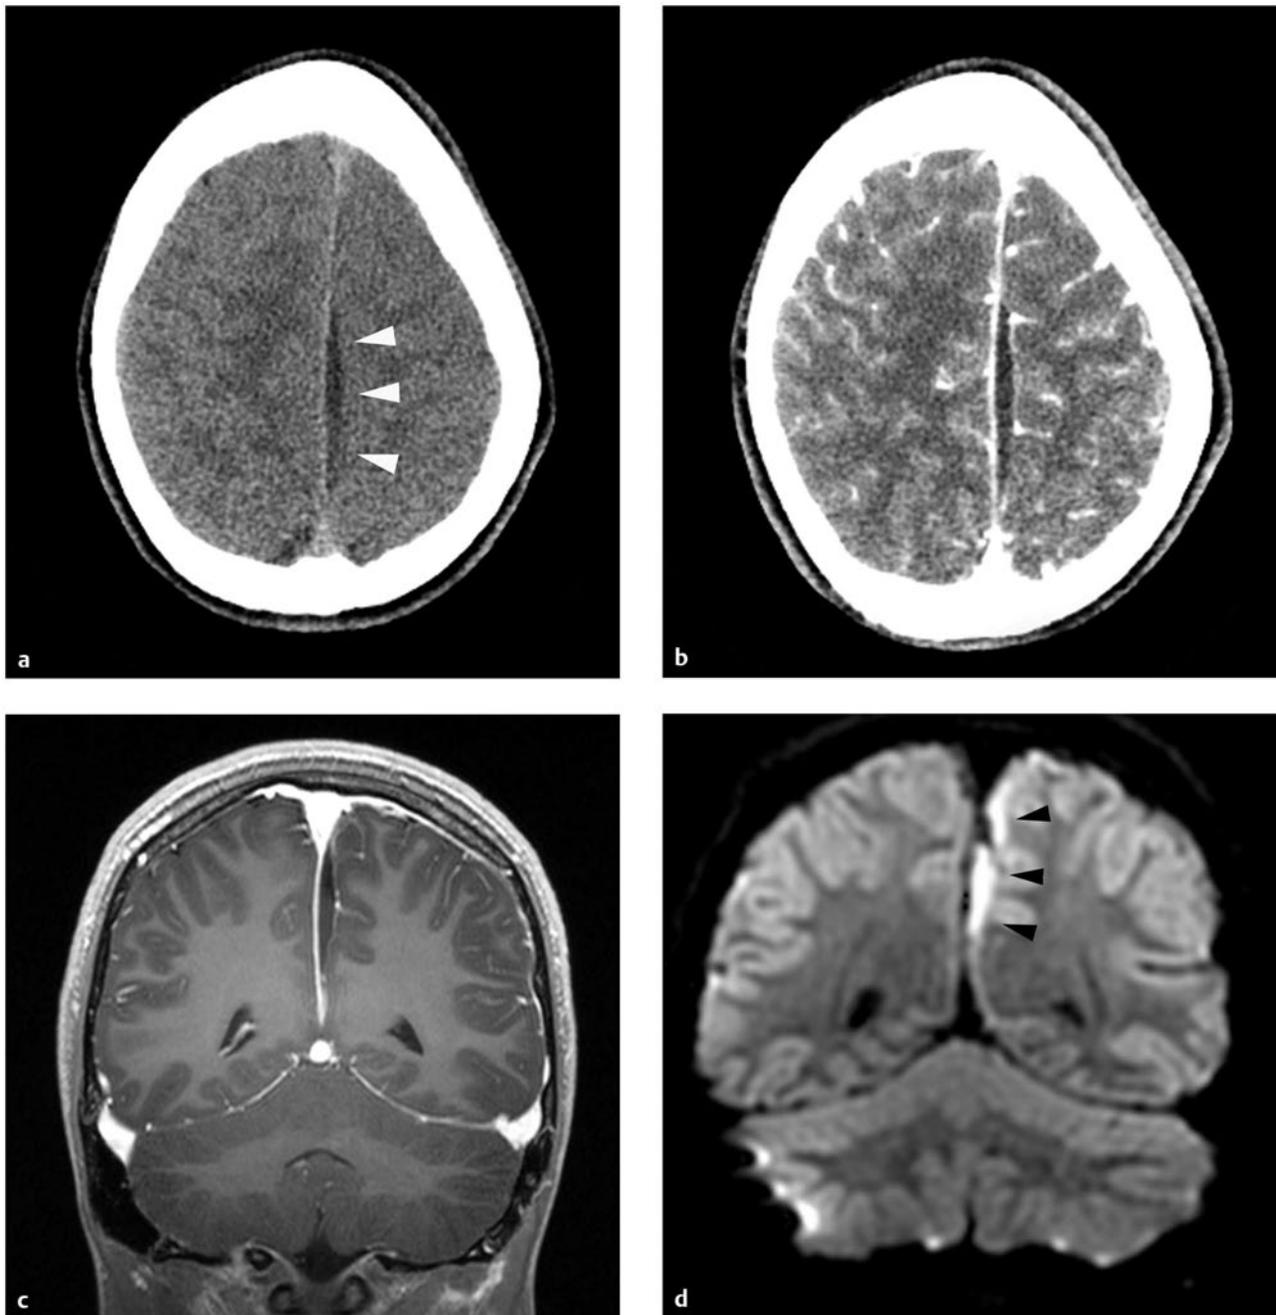

Fig. 78.3 (a) This school-age boy had headache and fever. He was lethargic at presentation, and there was a right lower limb monoparesis. After functional endoscopic sinus surgery for his associated frontal and ethmoid sinusitis, he received a 6-week course of parenteral antibiotics. There was no neurosurgical intervention. He recovered completely. Computed tomographic scan of the brain without contrast shows a small, low-density collection in the interhemispheric fissure (*white arrowheads*). (b) There is pachy- and leptomeningeal enhancement after contrast administration. (c) Likewise, there is pachy- and leptomeningeal enhancement on this coronal, T1-weighted magnetic resonance imaging sequence. The collection itself is low-intensity compared with brain. (d) On diffusion-weighted imaging, the interhemispheric pus is high-intensity (*black arrowheads*).

adjacent to subdural collections, and because the diffusion of water protons is restricted by the viscosity of pus, the collections themselves are distinct high-signal structures (► Fig. 78.3d)^{71–73} Conversely, purulent collections have low intensity on apparent diffusion coefficient (ADC) maps.^{71,72} Epidural abscesses may not restrict diffusion so consistently as subdural collections.⁷⁴ MR spectroscopy detects the elevated

lactate concentrations typical of purulent collections. Arterial spin labeling sequences document cerebral perfusion, and MR venography offers sensitive assessment of the dural venous sinuses. Many of these data, elegant as they are by historical standards, are of limited practical usefulness for treatment planning. The utility of imaging data for the prognostication of functional outcomes has not been analyzed extensively, but

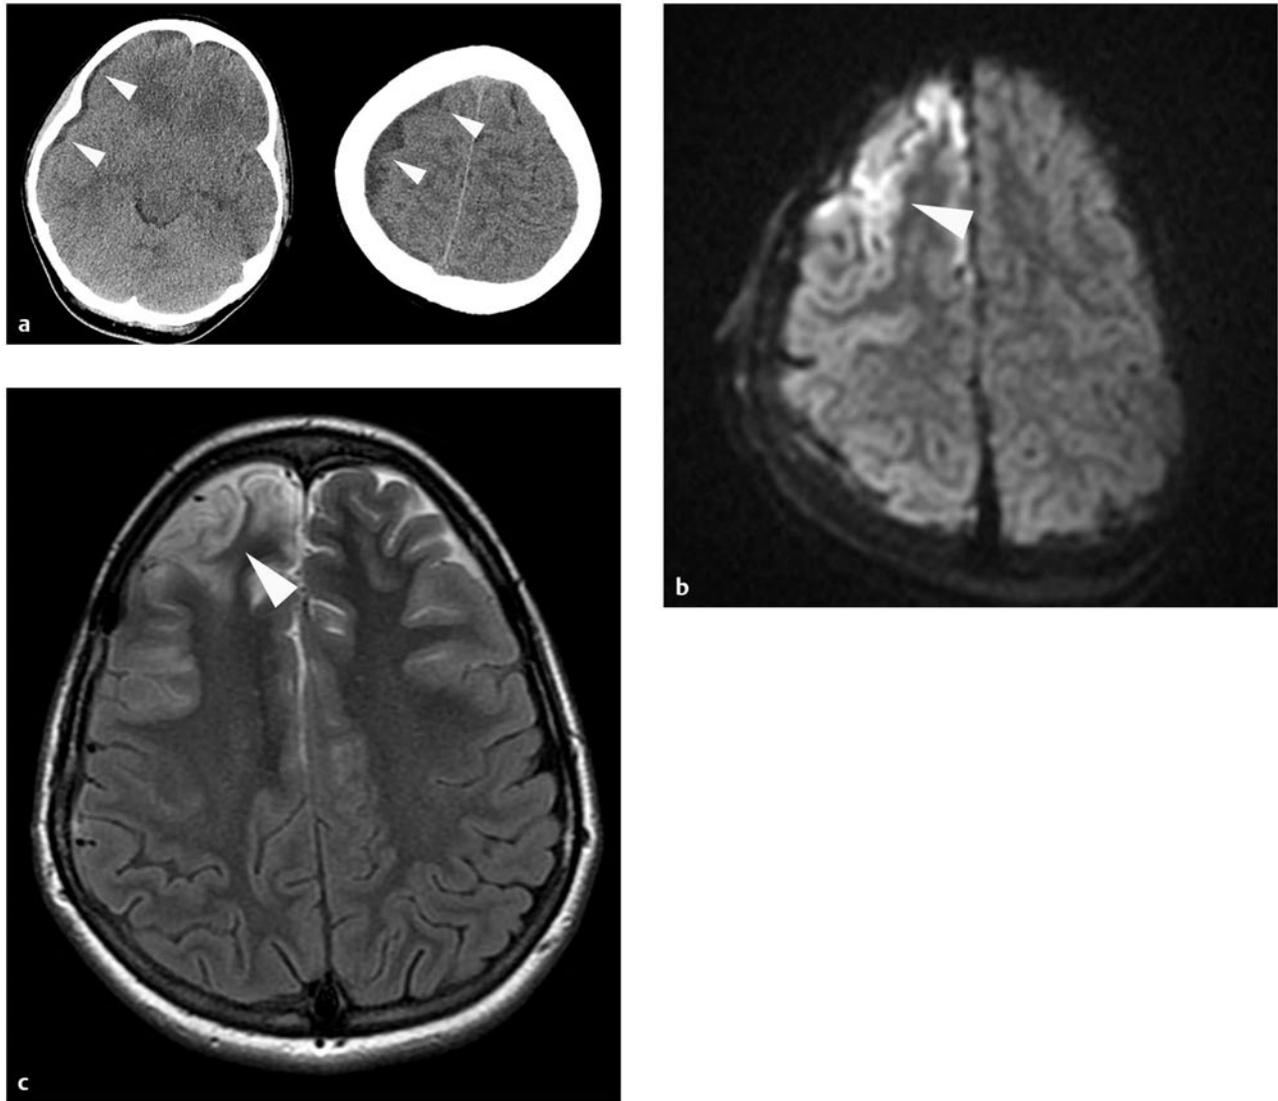

Fig. 78.4 (a) This school-age girl collapsed at home after several days of headaches and fevers. In the emergency department, she was noted to be hemiplegic on the left side. A computed tomographic scan of the head without contrast shows a thin, low-density subdural collection (white arrowheads) distributed widely over the right convexity. She underwent immediate osteoplastic right frontoparietotemporal craniotomy for drainage of her empyema. Her postoperative course was notable for septic shock requiring aggressive fluid resuscitation and pressors. (b) The diffusion-weighted image (DWI) from a study performed on the third hospital day shows high signal intensity in the cortical mantle of the right frontal lobe (*white arrowhead*). (c) At late follow-up, her hemiplegia had resolved completely, but she has persisting neurocognitive disabilities and is continuing in rehabilitation. This T2-weighted axial MR imaging sequence shows encephalomalacia (*white arrowhead*) at the site of the abnormality on the earlier DWI sequence.

patients with cortical ischemic changes on DWI sequences in the acute stages of their illness often exhibit encephalomalacic changes at the corresponding sites on late follow-up (► Fig. 78.4a–c). MR imaging is certainly the most sensitive technique for identifying small purulent collections adjacent to the skull and thus may be the technique of choice for monitoring response to antibiotic treatment.

78.2.7 Treatment

The primary treatment of intracranial suppuration of sinogenic or otogenic origin is antimicrobial.¹¹ The presence of subdural

or epidural pus is not by itself an indication for surgical drainage. Complete drainage of intracranial pus is not possible and is not necessary for cure. Indeed, in a recent cohort study based on a large administrative data set, more than 25% of patients with intracranial suppuration of sinogenic or otogenic origin were managed nonoperatively.⁶ The indications for surgical intervention are twofold: to obtain a microbiological diagnosis and to relieve symptomatic or threatening mass effect. The former indication often motivates urgent neurosurgical intervention at the time of presentation. The latter indication is clearly a matter for judgment based on careful assessment of the patient's clinical condition and imaging data. It may be present at

presentation, or it may arise at unpredictable times during the initial phase of treatment.⁵³ Surveillance imaging at frequent intervals allows close monitoring of the size and distribution of subdural collections.

A detailed discussion of antibiotic selection is beyond the scope of this chapter. In principle, therapy is guided by the sensitivities of the microbial isolates, but actual practice is not so intellectually satisfying. The administration of antibiotics before specimens can be obtained may compromise the sensitivity of culture methods. Although the concordance between intracranial cultures and sinus or ear cultures has been reported to be good,^{10,53,75} the relevance of extracranial cultures to intracranial suppuration is always uncertain, and the isolation of one organism does not eliminate the possibility of polymicrobial infection. Typically, three parenteral antibiotics must be employed at the outset to cover staphylococci, streptococci, gram-negative organisms, and anaerobes, and regardless of culture results, most patients are subjected to 6 weeks of broad-spectrum therapy.

Questions of surgical technique have been the topic of animated discussion in the literature, particularly for subdural empyema. Because surgery commonly must be undertaken on an urgent basis at odd hours, circumstances may favor the speed and simplicity of bur holes, and surgeons who feel compelled to discard craniotomy flaps elevated in the presence of pus naturally reserve craniotomy for patients who fail to respond to more limited interventions.⁵¹ This concern is misplaced. Craniotomy flaps elevated with an osteoplastic technique are highly resistant to infection, and under contemporary broad-spectrum antibiotic coverage, even free flaps heal reliably without complications.⁷⁶ On the other hand, many authorities have commented that patients treated initially with bur holes are subject to more frequent returns to the operating room for recurrent or new purulent collections than patients treated initially by craniotomy.^{1,8,13,16,77,78} In the very large case series of Nathoo and associates, craniotomy was associated with improved outcomes as well.¹ Craniotomy at presentation is the senior author's usual practice—an osteoplastic frontoparietotemporal craniotomy large enough for wide exposure of the more involved convexity and cautious drainage of the interhemispheric fissure, if necessary. And whatever may be the first intervention, reoperation for the reaccumulation of pus is so frequently necessary that this contingency must be born in mind in planning the initial exposure. Reoperation rates between 9 and 50% have been reported.^{1,5,8,77}

Subdural empyema of the posterior fossa is often diffusely distributed over the tentorial, petrosal, and occipital surfaces of the cerebellum, so a wide exposure is required.¹² Transient swelling of the cerebellum may necessitate leaving the craniotomy flap out and the dura unclosed. The senior author's usual practice in midline exposure of the posterior fossa is to leave a myofascial cuff along the nuchal line to permit reattachment of the cervical muscles to the occipital bone in the closure. This maneuver minimizes deformity and may reduce the risk for CSF-wound fistula when the dura must be left open in a large craniectomy defect. Posterior fossa subdural empyema is often complicated by hydrocephalus, which may be transient or persistent.¹⁰ In the large case series of Nathoo and associates, hydrocephalus developed in 77% of cases.¹²

External ventricular drainage is required in the acute phase, and a CSF shunt may be considered after the infection has been eradicated.

Surgery for epidural abscess differs in some respects. If a microbiological diagnosis has been obtained from sinus cultures, small collections may be managed nonoperatively.⁴⁶ Epidural abscesses are generally more focal than subdural empyemas, so drainage by bur holes often suffices.² Because most epidural abscesses are frontal, cosmetic considerations are pertinent. A bicoronal scalp incision for the drainage of frontal epidural collections can sometimes be avoided by employing an infraciliary incision and a small bur hole in the orbital roof to gain access to the anterior fossa directly or through the frontal sinus (► Fig. 78.5). The special case of Pott's puffy tumor raises the question of how to manage the associated osteomyelitis of the frontal bone. In the absence of a frank sequestrum, surgical restraint is in order. Craniectomy of the involved bone creates a skull defect with appalling cosmetic consequences and is generally unnecessary. Even a badly eroded frontal bone has the potential to heal solidly with a long course of antibiotic therapy (► Fig. 78.6a–d).

Most patients with sinogenic or otogenic intracranial suppuration require functional endoscopic sinus surgery or mastoidectomy at some point in time. There are no precise guidelines for whether and when these interventions may be indicated, so active communication with the consulting otolaryngologist is necessary. Coordinated drainage of intracranial and extracranial pus at the time of presentation has been advocated to minimize the risks for reaccumulation and antibiotic resistance,^{1,5,13,22,32} but controlled data are lacking.

The management of intracranial hypertension associated with subdural empyema has received little attention in the literature. Intracranial hypertension may be caused by the mass effect of the purulent collection itself, by hydrocephalus, or by cerebral venous thrombosis or dural sinus thrombosis. So far as possible, if a specific cause can be identified, it must be treated on its own terms. In the senior author's practice, the treatment of elevated intracranial pressure as a therapeutic goal in its own right proceeds by analogy with the management of severe traumatic brain injury. If the patient declines to a Glasgow Coma Scale score of 8 or less, intubation for controlled ventilation is undertaken, and intracranial pressure monitoring is indicated. Intracranial hypertension is managed by sedation, ventricular CSF drainage, and osmotic therapy with mannitol or hypertonic saline. If these measures do not suffice, lumbar CSF drainage, decompressive craniectomy, or barbiturate coma may be considered, just as for traumatic brain injury. Aggressive therapy is warranted. Although coma at presentation is a bad prognostic sign, patients who lapse into coma during treatment often make good recoveries.

Dogmatic guidance about the management of craniectomy flaps and skull defects after decompressive craniectomy in the clinical setting of suppuration is unwise, except to say that frankly osteomyelitic bone must be discarded. Craniectomy flaps in good condition may be frozen, if reliable local facilities are available, or stored in the subcutaneous tissues of the abdominal wall for later reconstruction. An interval of 3 to 6 months from the conclusion of antibiotic therapy is customary. Rates of recurrent infection after cranioplasty with stored bone in this clinical context are poorly defined.

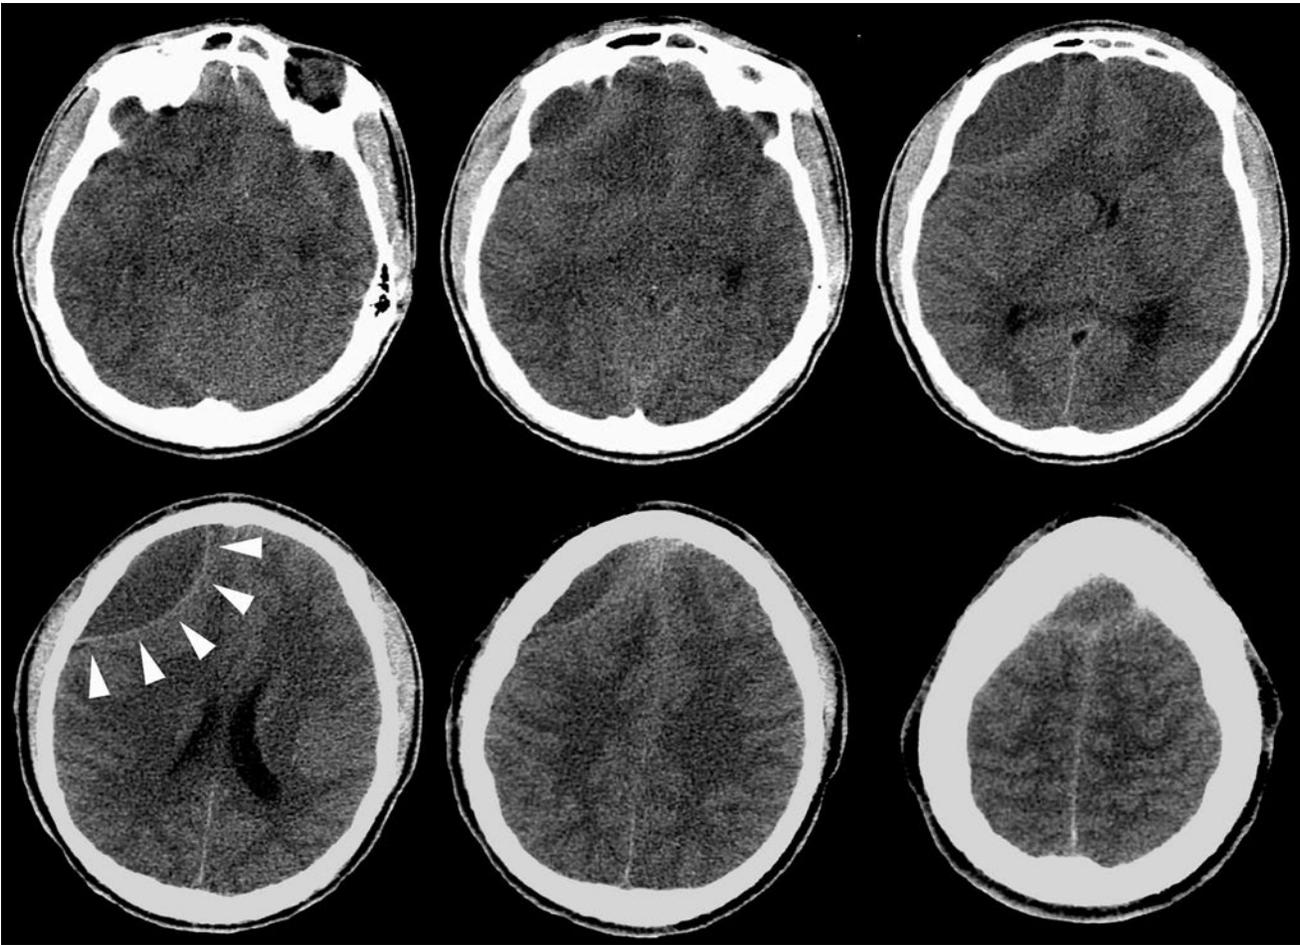

Fig. 78.5 This computed tomographic scan of the brain without enhancement shows a large anterior fossa epidural abscess. White arrowheads mark the biconcave contour. This collection was drained successfully through an infraorbital incision and a bur hole in the right orbital roof.

Seizures are a common complication of subdural empyema. A short course of prophylactic antiepileptic drug treatment is reasonable through the acute phase of the illness, by analogy with the management of severe traumatic brain injury. If actual seizures occur, the administration of antiepileptic drugs with maintenance of therapeutic blood levels under the supervision of a neurologist is appropriate.

Cerebral venous thrombosis and dural sinus thrombosis may complicate subdural empyema of sinogenic or otogenic origin. Focal thrombosis of the cerebral veins can in principle lead to venous infarction. This process was described clearly in the older autopsy literature,^{7,79} but it is seldom identified in contemporary clinical practice. If the thrombosis obstructs drainage through the sagittal or the dominant transverse or sigmoid sinus, it can cause diffuse cerebral venous congestion with a pseudotumor syndrome and intracranial hypertension. The most familiar clinical setting is sigmoid sinus thrombosis adjacent to an otitis or mastoiditis, and the consequent headaches, papilledema, and elevated opening pressure on lumbar puncture have been assigned the moniker “otitic hydrocephalus.”⁸⁰ The classic description of septic cavernous sinus thrombosis complicating acute sinusitis includes chemosis and proptosis from orbital venous congestion, ophthalmoplegia, visual loss due to retinal ischemia, and contralateral hemiplegia due to

thrombosis of the cavernous carotid artery. Fortunately, this entity is seen rarely, and even in the era before antibiotics its presentation was more commonly in fragments than in this fully elaborated picture.⁸¹ Septic thrombosis of the sigmoid or cavernous sinuses can extend into the internal jugular vein and generate septic embolization of the pulmonary circulation; this dangerous complication carries the eponym “Lemierre syndrome.”⁸² Dural sinus thrombosis can be demonstrated relatively readily by MR venography. Treatment measures include hydration, anticoagulation, surgical aspiration, and thrombectomy. For highly focal thromboses, endovascular thrombolysis may be considered, although the literature provides no guidance. Care must be exercised in balancing the clinical need against the risk for hemorrhagic complications, particularly in the context of recent or anticipated intracranial surgery.

78.2.8 Outcomes

Over time, the care of children with sinogenic and otogenic intracranial suppuration has been transformed by several readily identifiable advances. Before the introduction of antibiotics, subdural empyema was a uniformly fatal disease. With the appearance of penicillin and the sulfonamides, survival rates in

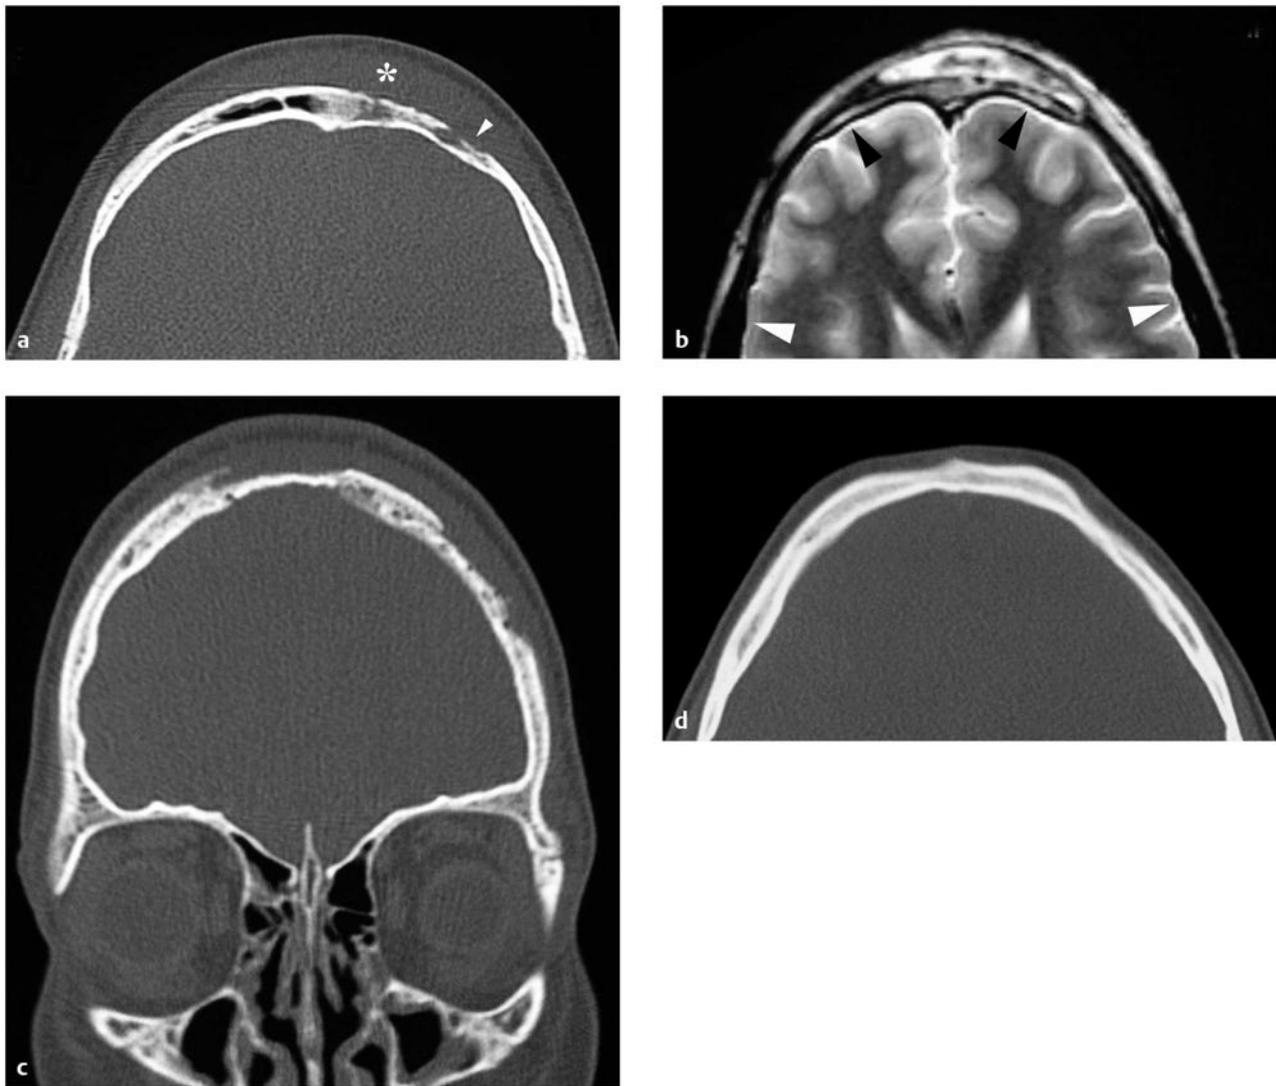

Fig. 78.6 (a) A male teenager came to attention with headache, fever, and extensive swelling of his forehead and scalp. This computed tomographic (CT) scan performed early in his course shows a large subperiosteal abscess (*white asterisk*) and osteomyelitis of the frontal bone with extensive erosive changes (*white arrowhead*). (b) This axial, T2-weighted MR imaging sequence shows high signal intensity, reflecting marrow edema in the involved frontal bone (*black arrowheads*), in comparison with the relatively uninvolved parietal bones (*white arrowheads*). There was no epidural abscess in this case. (c) Despite sinus drainage and parenteral antibiotics, the progress of the osteomyelitis was not arrested immediately. This coronal CT scan performed in the second week of treatment shows worsening erosion of the frontal bone. Extensive débridement of the frontal bone was considered, but it was deferred. (d) After 6 weeks of parenteral antibiotic therapy, the frontal bone healed. (Courtesy of Drs. Joseph Piatt, Jennifer Smith, and Eric Faerber.)

the neighborhood of 50% or better became possible.^{17,34,77,83,84} The development of computed brain imaging has simplified the diagnosis greatly, and its liberal employment in the course of treatment has facilitated not only prompt intervention for complications but also confident observation of stable or resolving collections. Concurrently, the introduction of third-generation cephalosporins, metronidazole, vancomycin, sulbactam, meropenem, and other advanced antibiotics has augmented the power of medical therapy. Contemporary mortality rates for subdural empyema are reported between 13% and nil,^{1,1.5,8-11,16,20,22,23,28,51,53} and there is now an expectation that isolated epidural abscess can be treated without mortality.^{2,8,9,22} Coma at presentation remains a grave

prognostic sign, but patients presenting with hemiparesis or other focal neurologic signs often make gratifying recoveries with little or no long-term disability.^{1,5,9,11,16,22,28,77}

78.2.9 Prevention

Because sinusitis, otitis, and mastoiditis are so common and commonly run such benign courses, and because their intracranial complications are so infrequent and threatening, there has been much bootless discussion about preventative measures. Intracranial suppuration has been blamed on delayed recognition of the preceding infection, inadequate treatment, delayed treatment, and poor compliance with

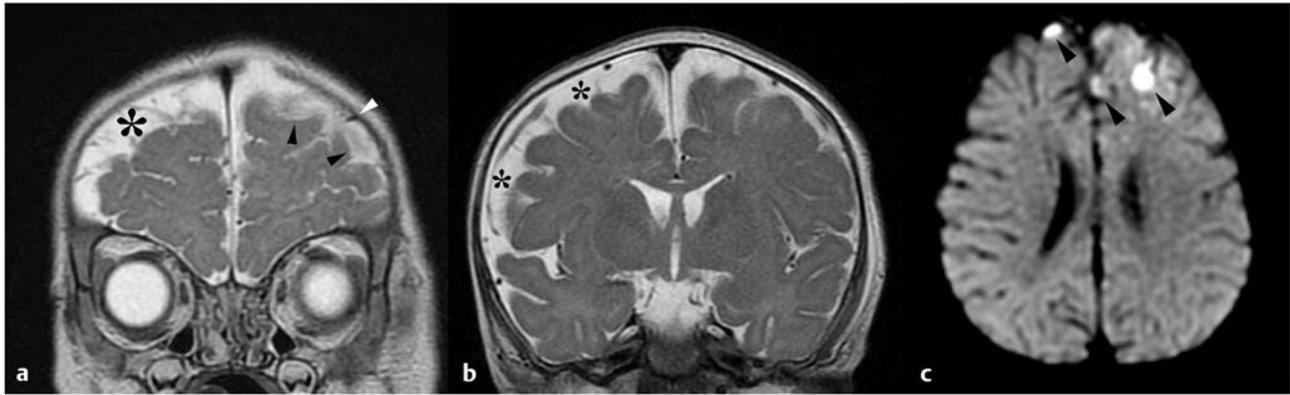

Fig. 78.7 (a) A 6-month-old infant developed pneumococcal meningitis. Coronal T2-weighted magnetic resonance imaging shows prominence of the subarachnoid spaces (black asterisks). Over the left frontal convexity is an extracerebral collection with intensity slightly lower than that of cerebrospinal fluid (black arrowheads). This collection is confirmed to be in the subarachnoid space by the presence of a vascular flow void (white arrowhead) within it. (b) Diffusion-weighted imaging sequence from the same study shows droplets of high-signal pus lying in a sulcus and (c) on the surface of several gyri (black arrowheads).

treatment.^{11,18,28} Although these factors may seem to contribute to individual anecdotal cases, systematic analysis is impossible. The degree to which these same factors are present in the overwhelmingly more numerous cases of predisposing head infections that do not progress to intracranial complications is unknowable. Numerous international authorities have developed guidelines for the management of bacterial sinusitis and otitis, but the prevention of complicating intracranial suppuration has fallen outside the scope of these efforts.^{85–88}

78.3 Meningitis

Subdural empyema complicating meningitis in infants and young children is much less common in contemporary North American practice than it was in the past century, before the adoption of universal immunization against *Haemophilus influenzae* and *Streptococcus pneumoniae*. Over time, as the incidence of this condition has plummeted, technological advances have transformed the simplicity and sensitivity of diagnostic methods. For this reason, most of the literature is either old or international, and its lessons require judicious application.

78.3.1 Pathology

Several distinct types of extracerebral collection can complicate the course of young children undergoing treatment for bacterial meningitis. In addition to subdural purulence indistinguishable from sinogenic subdural empyema, watery hypocellular fluid can collect in the subdural space—so-called subdural effusion. Meningitic subdural empyema can also be confused with focal collections of thick pus in the subarachnoid space. Distinction among these entities has obvious surgical implications: an effusion can be drained through a needle. Subdural empyema requires bur hole drainage or craniotomy. And there is no practical, safe technique for the drainage of subarachnoid pus. As will be seen, these entities can be distinguished with modern imaging methods.

78.3.2 Microbiology

As the population-based incidence of meningitis due to *H. influenzae* and *S. pneumoniae* has fallen, other organisms have accounted for larger fractions of cases of meningitic extracerebral collections—notably group B streptococci, enteric gram-negative organisms, and *Neisseria meningitidis*.^{8,37,89}

78.3.3 Clinical Presentation

Even among young children, the development of meningitic subdural collections seems to be a function of age; in one large case series that predated computed brain imaging, the prevalence ranged from 21% among infants younger than 6 months to only 2.6% in children in the second year of life. No collections were detected in older children.^{18,90} Meningitic extracerebral collections are seldom recognized at the time of diagnosis of the underlying meningitis; they are later-developing complications. The typical clinical presentation is recurrent or persistent fever or seizures in an infant or young child who seemed otherwise to have had a satisfactory initial response to antibiotic therapy.⁹¹ In one study, the prevalence rates of subdural empyema among infants with persisting fever at 9 days and in those with recurrent fever were 27% and 23%, respectively.⁹¹ In the era after antibiotics but before immunization and computed imaging, when this complication was more common, new focal neurologic deficits, depressed responsiveness declining to coma, and opisthotonus were described as well, but in that era, diagnosis was by subdural puncture. Such catastrophic presentations are unusual now.

78.3.4 Imaging

The imaging characteristics of meningitic subdural empyema generally conform to the descriptions of sinogenic and otogenic collections. On MR imaging, DWI sequences are especially sensitive. MR imaging also permits the distinction between purulent subdural collections and pus in the subarachnoid space itself. In the subarachnoid space, pus may appear as high-signal

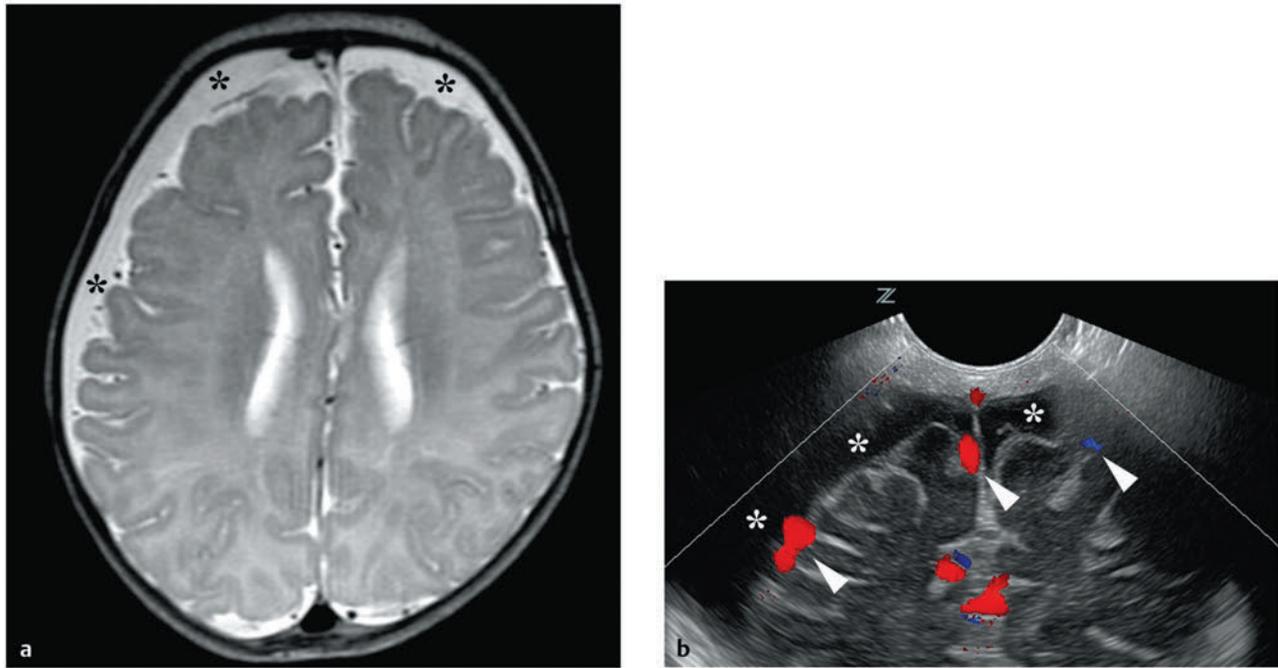

Fig. 78.8 (a) An infant with group B streptococcal meningitis underwent magnetic resonance imaging. This axial T2-weighted image shows bilateral subdural effusions (*black asterisks*). The subdural collections are homogeneous, with signal intensity close to that of cerebrospinal fluid. (b) Ultrasound examination of the brain of the same patient shows hypoechoic extracerebral collections (*white asterisks*), confirmed to be subdural by the close apposition to the cortical surface of the Doppler signals (*white arrowheads*) corresponding to vessels in the subarachnoid space.

droplets or as a laminar collection adherent to the surface of the brain (► Fig. 78.7a,b).⁹² Pus imaged in the subarachnoid space may have an internal structure produced by vascular flow voids, whereas subdural pus has homogeneous signal characteristics only sometimes interrupted by reactive, enhancing membranes. The signal characteristics of subdural effusions are close to those of water, and by definition effusions do not restrict diffusion.⁷¹

Among infants with open fontanels, ultrasound may be useful to distinguish reactive subdural effusions from empyema and empyema from subarachnoid pus.⁹³ Whether it is in the subdural space or in the subarachnoid space, pus is hyperechoic. In the subarachnoid space, echogenic inflammatory changes conform to the surface of the brain and fill the sulci. Subdural collections can be distinguished from the subarachnoid space by the additional presence in the latter of vascular Doppler signals (► Fig. 78.8a,b). Subdural effusions are hypo- or anechoic with floating particulate debris.

78.3.5 Treatment

The treatment of meningitic extracerebral suppuration has undergone a notable evolution over the history of the subspecialty of pediatric neurosurgery. McKay et al advocated craniotomy not only for the drainage of pus but more importantly for the stripping of inflammatory membranes off the pial surface of the brain.⁹⁴ They believed that the continuing presence of inflammatory membranes promoted the reaccumulation of pus and restricted subsequent growth of the brain. This dogma, which applied to chronic subdural hematoma as well as to

subdural empyema, was eventually overthrown by Shulman and Ransohoff, Collins and Pucci, Goodman and Mealey, and other worthies of the next generation, who observed that the natural history of subdural membranes is to disappear.^{95–97} Less radical interventions, including the novel pleural shunt, seemed to yield satisfactory outcomes.^{95,98,99} Nevertheless, diagnostic vigilance and assiduous drainage of all detectable subdural pus continued to be the guiding principles.

What has enabled the adoption of a more expectant approach has been the development and ready availability of computed imaging. Contemporary brain imaging gives the surgeon comprehensive data on the volume, distribution, and temporal evolution of extracerebral suppuration, and experience has shown that most of these collections resolve without drainage. The treatment of meningitic extracerebral suppuration is primarily the antibiotic treatment of meningitis. The indications for surgical intervention are symptomatic intracranial hypertension, threatening mass effect, or expansion on sequential imaging despite appropriate antibiotic therapy. When compelling indications exist for the drainage of collections, a graduated approach is appropriate, beginning with subdural puncture or bur holes (► Fig. 78.9).¹¹ Craniotomy is not required as often as for older children with sinogenic or otogenic suppuration. Chronic collections with accelerated head growth and craniocerebral disproportion can be managed with pleural or peritoneal shunts, although the senior author has never encountered such circumstances.

The question may arise of continuing culture positivity of the extracerebral collection as a possible indication for surgical intervention. In reports before and after the introduction of

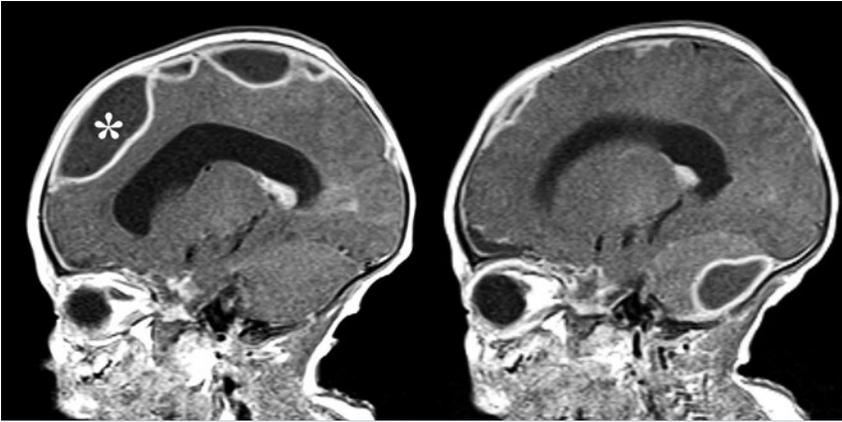

Fig. 78.9 This neonate developed subdural empyemas complicating *Escherichia coli* meningitis. The largest collection (white asterisk) was drained with a needle through the anterior fontanel. It was still culture-positive even though the cerebrospinal fluid (CSF) had been sterilized. Nevertheless, without any change in antibiotic therapy, after several weeks the other collections eventually resolved. The infant later required a CSF shunt for progressive hydrocephalus.

computed imaging, an offending organism was cultured from between 11 and 23% of subdural specimens.^{89,100–102} How this datum can affect treatment is a matter for discussion on a case-by-case basis. Regardless of culture results from a sample of subdural pus, patients who have had a complicated initial clinical course and have been recognized to have extracerebral collections are already committed to a longer course of antibiotic administration than the usual 10 to 14 days. Such patients can be managed safely by clinical observation and sequential imaging.

78.4 Trauma and Surgery

Extracerebral suppuration is very seldom encountered as a complication of elective surgery or surgery for trauma in pediatric practice. Aside from case reports, there is no literature devoted to the pediatric age group, and the largest series of cases of postsurgical and posttraumatic infection include very small numbers of children and fail to discuss them separately.^{62,103–105} Principles must be extrapolated from adult practice.

Risk factors are recognized: inadequate initial care of open traumatic wounds, multiplicity of previous craniotomies at the same site, previous surgery opening the facial sinuses, employment of synthetic dural substitutes or cranioplasty materials, previous radiation therapy, advanced age, and failure to administer prophylactic antibiotics.^{103–105}

The temporal course of infection varies. Subdural empyema and epidural abscess tend to present within a few weeks of the preceding operation. Osteomyelitis of the craniotomy flap—invariably associated with some degree of epidural pus—can appear after notoriously long latencies. Median times to the presentation of infections requiring surgical treatment have been reported in the neighborhood of 4 to 6 weeks.^{104,105}

In keeping with the hospital acquisition of infection, the predominant organisms are *Staphylococcus* species and gram-negative rods. As with sinogenic and otogenic suppuration, the possibility of polymicrobial infection must be considered, but anaerobes are less commonly encountered and tend to be gram-positive skin organisms, such as *Propionibacterium acnes* and diphtheroids.^{104–107}

Exploration of the wound is indicated. In this respect, postsurgical and posttraumatic infection differs from sinogenic, otogenic, and meningitic suppuration, for which closely observed medical management can be considered in selected cases. The collection must be cultured, and the wound must be débrided

of synthetic material and devitalized tissue. The disposition of the craniotomy flap itself is a matter for judgment. In cases of acute infection after a short latency, if osteomyelitis is not clearly established in the flap, it may be scrubbed with antibiotic or antiseptic solutions and replaced with reasonable hope of healing under the cover of a protracted course of parenteral and oral antibiotics.^{76,107} Salvage of frankly osteomyelitic craniotomy flaps by antibiotic wound irrigation has been described.^{106,108} Because living with a large skull defect is such an ordeal for most patients and families, strenuous efforts to preserve the craniotomy flap are appropriate. In large case series, more than one operation has been required in 44 to 55% of cases.^{103,104}

Controlled data are lacking, but when the treatment of postsurgical or posttraumatic infection has created a skull defect, deferral of cranioplasty for 3 to 6 months is common practice.¹¹

78.5 Conclusion

Although the presentation may be alarming, the attentive treatment of epidural abscess and subdural empyema yields good outcomes in the great majority of cases. These cases represent rewarding opportunities for application of the experience and skill of the neurosurgeon.

Pearls

- The primary indications for surgery are to obtain pus for microbiological diagnosis and to relieve threatening elevations of intracranial pressure.
- Frequent brain imaging early in the course of treatment is critical to monitor responses to antimicrobial therapy.
- Drainage must be undertaken for collections that enlarge during therapy.
- Surgical restraint is appropriate in the management of osteomyelitis of the skull in the setting of sinogenic or otogenic suppuration.

79 Brain Abscess and Encephalitis

Jonathan Pindrik and Edward S. Ahn

79.1 Brain Abscess

79.1.1 Overview

Intraparenchymal abscesses require early diagnosis and intervention to minimize morbidity and mortality in the pediatric population. Because of the wide variety of potential pathogens, microbiological evidence through culture data provides a foundation for diagnosis and treatment. Appropriate therapy of intracranial abscesses requires combined surgical and medical management and collaborative care. This chapter highlights the main diagnostic considerations and treatment options for brain abscesses in the pediatric population.

79.1.2 History

William Macewen recorded the first diagnosis of a pediatric brain abscess in 1876 by postmortem examination.^{1,2} Clinical suspicion arose because of the patient's symptomatology, while localization stemmed from neurologic assessment. The surgical management of brain abscesses became more widely used in the 1930s, shortly after Walter Dandy recorded the first attempted aspiration of an intracranial abscess in 1926.² Subsequently, Pennybacker achieved the first safe and effective surgical resection of a cerebellar abscess in 1948.³

79.1.3 Epidemiology

Children age 4 to 7 years comprise the group of pediatric patients most commonly affected by brain abscesses.¹ Of all intraparenchymal abscesses, nearly 25% occur in the pediatric population younger than age 15.⁴ Despite a low incidence of 4 cases per million, intraparenchymal abscesses require close attention in the pediatric population because they carry high risks for morbidity and mortality.^{1,5}

79.1.4 Pathology

An abscess is a well-circumscribed, encapsulated collection of purulent material containing microorganisms, inflammatory cells, cellular debris, and necrotic material.^{2,6} Abscess formation within the brain parenchyma proceeds through four stages (see box "Stages of Brain Abscess Formation (p. 1036)"). The initial stage of early cerebritis involves minimal central necrosis and surrounding edema, with subtle radiographic features. Imaging characteristics become more noticeable during late cerebritis, with early discontinuous sparse enhancement. During this phase, inflammatory cells congregate circumferentially around a necrotic core. Subsequently, during early capsule formation, fibroblasts create a thin capsule that exhibits contrast enhancement on computed tomography (CT) and magnetic resonance (MR) imaging. The late capsule stage displays greater contrast enhancement along a thicker, vascular, and more fibrotic abscess wall that surrounds a necrotic core.¹

Stages of Brain Abscess Formation

- Stage I: Early cerebritis
 - Days 1–3
 - Small area of central necrosis
 - Surrounding edema
 - Head computed tomographic findings variable but typically not prominent; hypodensity or faint contrast enhancement possible
- Stage II: Late cerebritis
 - Days 4–9
 - Necrotic core
 - Surrounding inflammatory cells
 - Early patchy enhancement on imaging
 - Thicker rim of peripheral enhancement later on imaging
- Stage III: Early capsule formation
 - Days 10–14
 - Necrotic core
 - Thin capsule formed by fibroblasts
 - Distinct rim enhancement on imaging
- Stage IV: Late capsule stage
 - Day 15 and beyond
 - Necrotic core
 - Thicker vascular capsule with increased fibrosis
 - Thicker rim of peripheral enhancement on imaging

79.1.5 Pathophysiology

Various mechanisms and underlying conditions account for the occurrence of intracranial abscesses. Potential etiologies include seeding from penetrating trauma, local spread of a contiguous infection, hematogenous spread of a distant infection, predisposition due to congenital abnormalities, and complications of an intracranial procedure. Patient characteristics and environmental factors influence the specific mechanism of brain abscess formation. For instance, neonates and infants display higher rates of cerebral abscess formation due to hematogenous dissemination and bacterial meningitis.¹ In developing nations, the contiguous spread of suppurative otitis media is a predominant cause of intraparenchymal abscesses.^{1,2,7}

Contiguous Spread

The intracranial spread of nearby infections typically occurs through necrotic tissue or focal areas of osteomyelitis.⁵ For instance, contiguous spread via the labyrinthine system or tegmen tympani may account for temporal or cerebellar abscesses resulting from mastoiditis or otitis media.¹ Contiguous spread of infection may also occur through the vasculature. Small, valveless diploic veins traverse the sinus walls and communicate with the dural venous plexuses, offering routes of entry for

Table 79.1 Common characteristics of pediatric brain abscesses based on predisposing condition and mechanism of infection

Predisposing condition	Mechanism of infection	Typical abscess location	Common microorganisms
Penetrating head trauma	Direct inoculation	Any intraparenchymal site	<i>Staphylococcus aureus</i> , viridans streptococci, <i>Streptococcus pneumoniae</i> , Enterobacteriaceae
Prolonged bacteremia, endocarditis	Hematogenous spread (remote location)	Arterial distribution, especially middle cerebral artery territory	<i>S. aureus</i> , streptococci
Sinus or dental infection	Contiguous spread Local venous spread	Frontal lobes	Gram-positive cocci and gram-negative bacilli; streptococci (e.g., <i>Streptococcus milleri</i>), <i>S. aureus</i> , Enterobacteriaceae
Chronic otitis media or mastoiditis	Contiguous spread	Temporal lobes, cerebellum	Gram-negative bacilli, streptococci (aerobic and anaerobic), Enterobacteriaceae, <i>Pseudomonas aeruginosa</i> , <i>S. aureus</i>
Congenital cyanotic heart disease	Right-to-left shunting, paradoxical emboli	Arterial distribution, especially middle cerebral artery territory	Gram-positive cocci, viridans streptococci
Immunocompromised status	Opportunistic infections	Arterial distribution, any intraparenchymal site	Fungi, yeast: <i>Candida</i> , <i>Aspergillus</i> , Mucorales
Immunodeficient status (AIDS)	Opportunistic infections	Any intraparenchymal site	<i>Toxoplasma gondii</i> , <i>Nocardia</i> , <i>Mycobacterium</i>
Ventriculoperitoneal shunt	Foreign body, ascending infection	Along proximal catheter trajectory; may include ventriculitis	<i>S. aureus</i> , <i>Staphylococcus epidermidis</i> , gram-negative bacilli, <i>P. aeruginosa</i>

infections involving the paranasal sinuses.⁵ Local infections predisposing to intraparenchymal abscesses include otic, dental, sinus, facial, and periorbital infections.

Predisposing Conditions

Several predisposing conditions in children relate directly to the mechanisms of intracranial infection (► Table 79.1). Congenital cardiac disease is an underlying abnormality in nearly 30% of children with intraparenchymal abscesses.¹ Cardiac anomalies include tetralogy of Fallot, transposition of the great vessels, atrial or ventricular septal defects, and Eisenmenger syndrome. The right-to-left shunt created in cyanotic heart disease allows the passage of paradoxical emboli and intracranial seeding via hematogenous spread.^{1,4,6} Immunosuppression is another important predisposing factor for brain abscess formation. Incompetence of the immune system occurs in the setting of immunosuppression for organ transplant, chemotherapy for malignancy, or underlying diseases like acquired immunodeficiency syndrome (AIDS). Pulmonary conditions, including cystic fibrosis and bronchiectasis, increase the risk for respiratory infections that may lead to brain abscess formation. Intracranial abscesses may also arise because of congenital abnormalities like dermoid cysts and dermal sinus tracts, which allow the direct invasion of microorganisms.^{8,9}

Trauma and Foreign Bodies

Penetrating trauma is a common cause of pediatric intracranial infection due to retained foreign debris or skull fragments. Often planted deep within the brain, such material cannot be

removed safely and serves as a nidus for infection.¹ Up to 13% of brain abscesses result from penetrating craniofacial trauma. Conversely, in from 5 to 16% of cases, penetrating head trauma leads to intraparenchymal abscess formation.¹ Other intracranial foreign bodies, such as ventricular shunts for hydrocephalus, also predispose to abscess formation. Microorganisms may colonize an intracranial catheter or ascend a distal catheter from the peritoneal space. Despite these plausible mechanisms, intraparenchymal abscesses associated with ventricular shunts occur infrequently.¹⁰ Although various mechanisms and predisposing conditions have been described, nearly 30% of intraparenchymal abscesses occur without an identified etiology.^{1,4}

Abscess Location

The specific location of an intraparenchymal abscess may reflect the mechanism of disease spread (► Table 79.1). For instance, abscesses in the distribution of the intracranial arterial circulation, especially the middle cerebral artery (MCA), suggest hematogenous dissemination from a remote source.^{4,6} Local venous drainage of sinus, dental, or facial infections into the cavernous sinus may lead to frontal lobe abscesses via retrograde thrombophlebitis.¹ Additionally, frontal abscesses may arise from dental or sinus infections via contiguous spread.^{4,6} Temporal lobe or cerebellar abscesses may suggest direct invasion from mastoiditis or chronic middle ear infections.⁴⁻⁶ Infratentorial abscesses may result from infection of posterior fossa dermoid cysts and associated dermal sinus tracts.^{3,8} The locations of intraparenchymal abscesses also correlate with age. Younger patients have higher rates of cerebellar abscesses, whereas older children have a higher incidence of temporal lobe abscesses.⁶

79.1.6 Microbiology

The specific type of infecting microorganism depends on patient characteristics and mechanism of disease (► Table 79.2). Gram-positive cocci, including *Streptococcus* and *Staphylococcus* species, are the most common group of microorganisms found in pediatric brain abscesses.^{1,2,6} Gram-negative rods, including the Enterobacteriaceae family and *Haemophilus* species, are the next most common group of pathogens implicated. Facultative and obligate anaerobic organisms are the predominant isolates reported in intracranial abscesses historically.⁵

Subpopulations of children exhibit trends with respect to infecting microorganisms. For instance, immunocompromised children show a higher frequency of intraparenchymal abscesses infected with fungi, yeast, *Nocardia*, *Toxoplasma gondii*, and *Mycobacterium tuberculosis*.^{4,5} The rising prevalence of these infections results from increasing rates of AIDS, chemotherapy, and immunosuppression.² In the neonatal population, *Citrobacter* is the most common cause of brain abscesses, especially in the setting of meningitis.^{1,6} Intraparenchymal abscesses associated with cyanotic congenital heart disease tend to be infected with viridans streptococci and other gram-positive cocci.⁵ Similarly, intracranial penetrating trauma predisposes to brain abscesses infected with *Staphylococcus aureus*, viridans streptococci, and *Streptococcus pneumoniae*.⁵ Intraparenchymal abscesses associated with ventriculoperitoneal shunts frequently exhibit culture isolates of *S. aureus* and *Staphylococcus epidermidis*, enteric gram-negative bacilli, and *Pseudomonas aeruginosa*.⁵ Delayed abscesses with *Propionibacterium acnes* may form along a retained ventricular catheter.¹¹ Multiple organisms may be present in up to 30% of brain abscesses; alternatively, many abscesses lack remarkable culture results.⁴

79.1.7 Clinical Presentation

Generalized Findings

Children with brain abscesses often present with symptoms related to infection and elevated intracranial pressure (ICP). Although common, the classic triad of fever, headache, and focal neurologic deficit is not present in the majority of patients.^{4,12} Up to 70% of children with an intraparenchymal abscess present with fever.^{1,4} Furthermore, most pediatric patients with an intraparenchymal abscess present with at least one symptom or sign of elevated ICP, including headaches, emesis, and papilloedema.⁴ Neonates with elevated ICP may show fullness or bulging of the anterior fontanel and increasing head circumference.⁶

A patient's neurologic status may be subtle confusion, lethargy, stupor, or coma depending upon the time of presentation and fulminance of disease.⁶ Coexistent meningitis may contribute to a declining neurologic status.³ Any acute decrement in the examination findings or Glasgow Coma Scale score can signify intraventricular extension of the abscess contents, a highly morbid and potentially fatal occurrence.^{1,6}

Neurologic Deficits

As with most intracranial lesions, the location, size, and surrounding edema of a brain abscess dictate the neurologic findings. Focal neurologic signs or seizures occur in 25 to 50% of pediatric patients with brain abscesses.⁴ Seizures are a

presenting symptom in nearly 27% of children with intraparenchymal abscesses.² Frontal lobe lesions often lead to personality or behavioral changes, difficulty with cognitive processes, or disinhibition.⁶ Additionally, contralateral motor weakness may develop from mass effect on the motor cortex. Cerebellar lesions may produce gait or limb ataxias, incoordination, eye movement abnormalities, or symptoms of elevated ICP due to obstructive hydrocephalus. Abscesses within the brainstem can cause cranial nerve deficits (cranial nerves III, VI, and VII) or upper motor tract signs.¹³

Parietal and temporal lobe abscesses cause deficits depending upon laterality and the structures involved. Nondominant parietal lesions may lead to contralateral hemineglect, dyspraxia, and visual field cuts. Abscesses in the parietal lobe of the dominant hemisphere may cause subtle dysphasias and visual field cuts as well. Visual deficits resulting from parietal lesions range from contralateral inferior quadrantanopsia to homonymous hemianopia depending upon involvement of the optic radiations.⁶ Temporal lobe abscesses may also cause visual field cuts. Additionally, abscesses within the temporal region of the dominant hemisphere may lead to pronounced aphasia.

79.1.8 Diagnosis

Imaging Findings

CT and MR imaging of the head have significantly improved the early diagnosis of brain abscesses. Ultrasonography of the head can also be used intraoperatively or in infants with open fontanelles. With greater speed and ease of acquisition than MR imaging, CT of the head typically portrays a centrally hypodense lesion with a peripheral rim of contrast enhancement.² Surrounding hypodensity typically indicates vasogenic edema (► Fig. 79.1). The findings on CT of the head may lag the clinical presentation; therefore, a lack of noteworthy findings should not exclude the diagnosis of brain abscess initially.⁴

Offering greater anatomical detail, MR imaging provides a better characterization of abscess size, location, quantity, and relation to neighboring structures.⁶ T2-weighted sequences depict a centrally hyperintense lesion with a hypointense rim and surrounding increased signal, consistent with vasogenic edema (► Fig. 79.2). Gadolinium administration on T1-weighted imaging portrays a centrally hypointense lesion with a peripheral rim of contrast enhancement (► Fig. 79.3). MR imaging also offers enhanced visualization of satellite lesions, cerebritis, and the differentiation between edema and liquefactive necrosis.¹ The MR imaging characteristics of an intraparenchymal abscess mirror those of other intracranial lesions in a child; the differential diagnosis broadly includes tumor, tuberculoma, cysticercosis, and vascular lesions.¹

Specialized MR imaging sequences allow further differentiation between brain abscesses and similarly appearing lesions. Diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) mapping help distinguish brain abscesses from cystic or necrotic tumors. A purulent abscess cavity typically exhibits high signal intensity on DWI but hypoattenuation on ADC mapping, consistent with diffusion restriction (► Fig. 79.4 and ► Fig. 79.5).^{14,15} In contrast, the cystic or necrotic portions of brain tumors typically appear hypointense on DWI with elevated ADC values. Exceptions to the DWI and ADC patterns may

Table 79.2 Microorganisms isolated in pediatric brain abscesses

Domain	Microbiological descriptors	Genus and species	Common patient characteristics	Additional comments
Bacteria	Aerobic and facultatively anaerobic, gram-positive cocci	<i>Streptococcus pneumoniae</i>	Meningitis, head trauma	
		Viridans streptococci	Cyanotic congenital heart disease, head trauma	
		<i>Streptococcus milleri</i> group	Child beyond neonatal period	Subgroup of viridans streptococci, also referred to as <i>Streptococcus anginosus</i> ; microaerophilic
		<i>Staphylococcus aureus</i>	Head trauma, sinusitis, ventricular shunt, chronic otitis media	Increasing prevalence of methicillin-resistant <i>S. aureus</i> (MRSA)
		<i>Staphylococcus epidermidis</i>	Ventricular shunt	Create biofilms adherent to catheters
	Facultatively anaerobic, gram-positive bacilli	<i>Listeria monocytogenes</i>	Immunocompromised host, neonate	Sensitive to ampicillin
	Aerobic, gram-positive bacilli	<i>Nocardia</i> species	Immunocompromised host, AIDS	Often confused with tuberculosis because of acid-fast staining and filamentous structure
	Facultatively anaerobic, gram-negative bacilli; Enterobacteriaceae family	<i>Escherichia coli</i>	Ventriculoperitoneal shunt	Sensitive to third-generation cephalosporins
		<i>Klebsiella</i> species	Ventriculoperitoneal shunt	Sensitive to third-generation cephalosporins
		<i>Proteus</i> species	Ventriculoperitoneal shunt, otic infection	Sensitive to third-generation cephalosporins
		<i>Enterobacter</i> species	Ventriculoperitoneal shunt, otic infection	Sensitive to fourth-generation cephalosporins
		<i>Citrobacter</i> species	Neonate, infant; meningitis	Most common microorganisms in neonatal brain abscesses
	Anaerobic, gram-negative bacilli	<i>Bacteroides</i> species	Chronic otitis media, mastoiditis, sinusitis	Most common anaerobic organisms found in temporal lobe abscesses due to otic infection
	Aerobic, gram-negative bacilli	<i>Pseudomonas aeruginosa</i>	Ventriculoperitoneal shunt, chronic otitis	Also present in immunodeficient hosts
	Aerobic and facultatively anaerobic, gram-negative bacilli	<i>Haemophilus influenzae</i>	Meningitis, chronic sinusitis	Sensitive to third-generation cephalosporins
	Aerobic, acid-fast bacilli	<i>Mycobacterium tuberculosis</i>	Immunodeficient host, AIDS	
Fungi	Branching pattern of septate hyphae	<i>Aspergillus</i>	Immunocompromised host	Typically spread from paranasal sinusitis or respiratory infections
	Dimorphic mycelial and yeast forms	<i>Coccidioides immitis</i>	Immunocompromised host	Geographic predominance in southwestern United States, Central and South America
	Budding yeast	<i>Cryptococcus neoformans</i>	Immunodeficient host, AIDS	Sensitive to amphotericin B and flucytosine
Protozoa	Infectious cyst form	<i>Toxoplasma gondii</i>	Immunodeficient host, AIDS	Increasing prevalence in regions where AIDS is endemic
	Trophozoite and cyst forms	<i>Entamoeba histolytica</i>	Developing nations, immigrants to United States	Sensitive to metronidazole

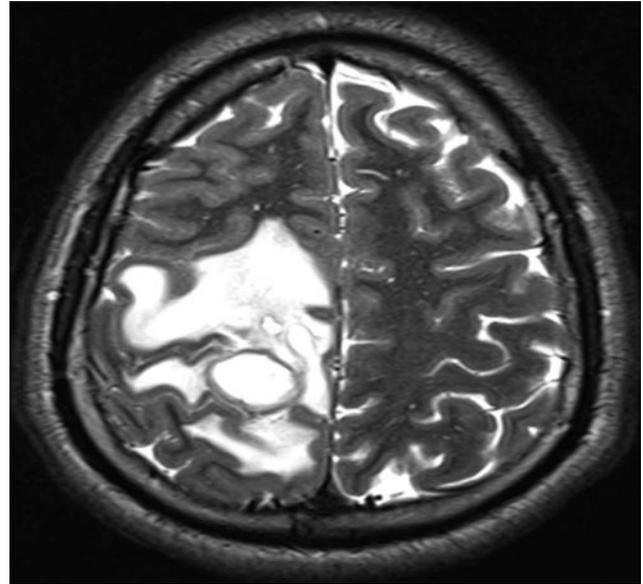

Fig. 79.2 Axial T2-weighted magnetic resonance imaging sequence depicting a right parietal intraparenchymal abscess with surrounding hyperintense vasogenic edema.

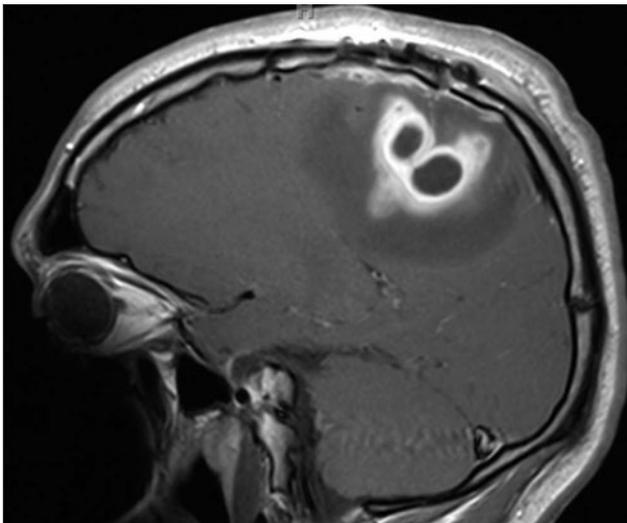

Fig. 79.3 Sagittal T1-weighted magnetic resonance imaging sequence with gadolinium administration showing peripheral contrast enhancement surrounding a hypointense core.

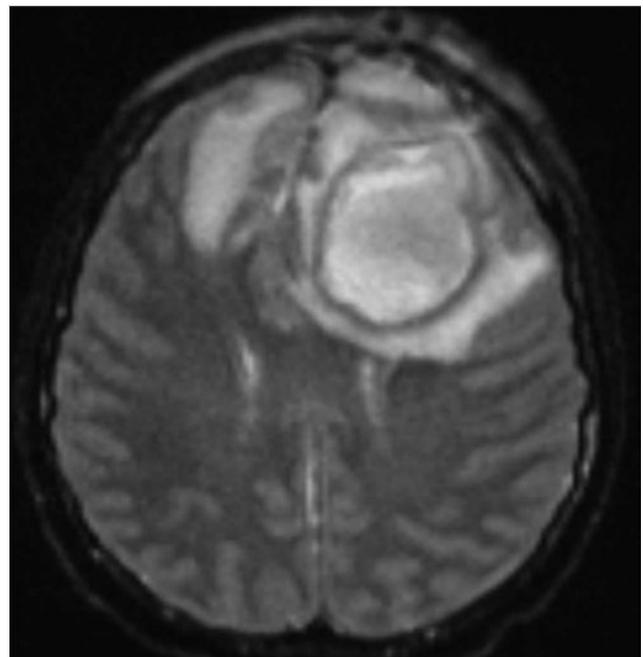

Fig. 79.4 Axial diffusion-weighted imaging sequence displaying the high-intensity inner contents of a left frontal brain abscess.

occur with toxoplasmosis abscesses and low-grade fibrillary astrocytomas.¹⁴

MR spectroscopy may also help narrow the differential diagnosis between cystic neoplasms, necrotic tumor, and purulent collections.² The existence of resonance peaks for succinate, acetate, lactate, and amino acids (such as valine and leucine) within the central cavity suggests the presence of a brain abscess.¹⁶ In contrast, cystic or necrotic tumors may exhibit a resonance peak only for lactate.¹⁷ MR spectroscopy combined with DWI and ADC mapping supplement conventional MR imaging findings in the diagnosis of pediatric brain abscesses.

Laboratory Studies

Multiple laboratory markers indicate the presence of infection in the setting of an intracranial abscess. These include peripheral leukocytosis and elevation of the C-reactive protein level and erythrocyte sedimentation rate. Lumbar punctures to acquire cerebrospinal fluid (CSF) are often contraindicated or

Fig. 79.5 Axial magnetic resonance imaging sequence with apparent diffusion coefficient mapping portraying low signal intensity of the central portion of the same left frontal brain abscess shown in ► Fig. 79.4.

provide a low yield in the setting of intraparenchymal abscesses.^{1,4,6} The CSF may show mild pleocytosis and an elevated protein level but typically exhibits a normal glucose concentration. Except with ventriculitis, the CSF Gram stain and cultures remain bland and sterile.⁶ Occasionally, culture data from blood or a contiguous site of infection suggest the culprit microorganism. However, blood cultures produce positive results in only a minority of cases.⁴

Additional Studies

In addition to defining an intraparenchymal abscess, the diagnostic work-up should search for predisposing factors. Concern for related sinus infections should prompt appropriate diagnostic imaging of the maxillary, ethmoid, frontal, and sphenoid sinuses (► Fig. 79.6). Because of the prevalence of cardiac anomalies and endocarditis in this population, echocardiography is an important tool in the diagnostic armamentarium. A thorough dental evaluation in children with brain abscesses may also reveal a surreptitious site of infection.⁶ In the absence of cardiac defects or obvious sites of contiguous infection, an evaluation for pulmonary infections or immunodeficiency may be valuable.

79.1.9 Treatment

Indications for Surgical Treatment

Like other intracranial lesions, brain abscesses warrant surgical consideration based on size, location, mass effect, and the patient's neurologic condition. In general, abscesses with a diameter larger than 2 to 3 cm deserve surgical attention because of mass effect.^{1,2,4,6} Furthermore, infratentorial abscesses merit

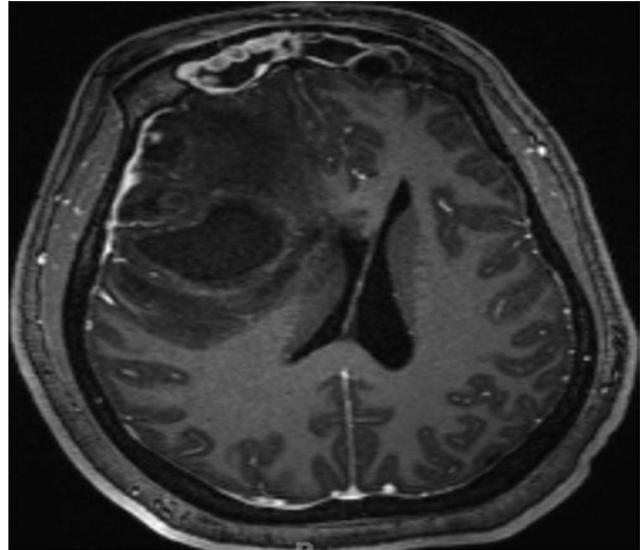

Fig. 79.6 Axial T1-weighted MR imaging sequence with gadolinium administration showing a right frontal intraparenchymal abscess with additional findings of bilateral frontal sinusitis and abnormal contrast enhancement.

surgical consideration because of the limited volume of the posterior fossa and risks for obstructive hydrocephalus or brainstem compression. Surgical intervention offers advantages of lowering the ICP and reducing mass effect, critical in children presenting with poor neurologic status. Additionally, surgical sampling usually provides a definitive diagnosis and identifies the offending microorganism.^{1,2,4} Surgical drainage also allows greater antibiotic efficacy; some antimicrobials lose their effectiveness when encumbered by many bacteria.^{2,4} Certain abscesses, including those in which *Nocardia*, helminths, parasites, or fungi are involved, respond poorly to medical therapy alone, requiring additional surgical intervention.⁴

Surgical Treatment

Surgical approaches for the treatment of brain abscesses include stereotactic needle aspiration and open excision. Both methods acquire samples for culture data and potentially alleviate mass effect. However, the two approaches differ greatly in regard to operative planning and invasiveness.

Stereotactic Needle Aspiration

Operative Technique

Stereotactic needle aspiration is a minimally invasive surgical approach to sampling and draining brain abscesses. The technique may be performed freehand or with intraoperative image guidance. Following appropriate placement of a standard bur hole or minimal craniotomy, the aspirating device can be advanced slowly into the necrotic core of the abscess. Intraoperative ultrasonography may help locate the abscess in real time during surgery. The biopsy needle trajectory should be chosen to avoid major vessels and eloquent cortex when possible. In rare cases of brainstem abscesses, transcerebellar or precoronal right paramedian transfrontal approaches have been used.^{1,13}

After the aspiration of purulent material, irrigation of the abscess cavity with antibiotic-impregnated fluid may enhance the treatment effect.¹ Stereotactic aspiration may be repeated in the context of multiple, residual, or recurrent abscesses.²

Advantages and Disadvantages of Stereotactic Aspiration

Stereotactic needle aspiration of brain abscesses offers several advantages over open craniotomy. As a minimally invasive approach, this technique involves less cortical exposure and damage to surrounding tissue.⁴ Aspiration allows the efficient decompression of purulent material in a relatively safe manner, with generally fewer complications than open approaches.^{1,2} Deep-seated lesions or those within eloquent cortex can be approached readily with needle biopsy, avoiding the greater risks of surgical excision. Brainstem abscesses, although accounting for fewer than 1% of intraparenchymal abscesses, similarly are favorable targets for minimally invasive techniques.¹³ Stereotactic aspiration also offers a safe approach to multiple brain abscesses in disparate regions. Finally, stereotactic aspiration can be used to approach abscesses in all stages of development, including early cerebritis, with a diagnostic yield near 95%.¹

Despite the numerous advantages of stereotactic aspiration, this minimally invasive technique may prove inadequate in certain settings. Aspiration may fail to decompress certain abscesses completely and may not prevent purulent reaccumulation. Suboptimal decompression may result from the high viscosity of purulent fluid or intra-abscess septa.¹³ Residual abscesses may require repeated stereotactic aspiration or the consideration of more aggressive surgical intervention.

Craniotomy and Abscess Resection

Operative Technique

Open craniotomy with lesion resection is an alternative approach to treating pediatric brain abscesses. Surgical excision also may be carried out with intraoperative image guidance. Wider calvarial opening and cortical exposure allow en bloc resection of the abscess wall and inner contents. During exposure and circumferential dissection, transcortical aspiration may be used urgently in the context of herniation. Once this and anesthetic maneuvers (hyperventilation, elevation of the head of the bed, administration of mannitol) lower the ICP, attention may be shifted to the abscess wall. However, friability of the parenchyma, proximity to eloquent cortex, and hemorrhage may preclude complete capsule resection. In addition to abscess removal, surgical excision allows the extrication of foreign bodies or skull fragments. Consequently, open craniotomy is the favored approach in brain abscesses secondary to penetrating head trauma.¹

Advantages of Open Craniotomy

Open craniotomy for abscess excision offers several benefits over stereotactic aspiration and nonsurgical management. The greater extent of pathologic tissue removal reduces concerns for residual mass effect postoperatively. Complete resection of the abscess capsule provides more tissue for histologic analysis, definitive therapy, and lower recurrence rates.^{1,3,8} Surgical excision generally offers the additional benefit of a shorter duration of antibiotic therapy postoperatively (3 to 4 weeks).⁴

Poor neurologic status of the patient also may necessitate more aggressive approaches up front. For instance, impending herniation may warrant open surgical intervention initially to lessen mass effect and maximize decompression.

Several types of pediatric brain abscesses, in addition to those associated with trauma, warrant strong consideration of open excision. Cerebellar abscesses may require open surgical intervention because of the confined space of the posterior fossa and concern for mass effect, obstructive hydrocephalus, or brainstem compression.^{1,2,4} In this context, suboccipital craniotomy allows wide posterior fossa decompression in addition to abscess resection.^{2,3} Multiple reports suggest lower rates of mortality and postoperative hydrocephalus with open resection than with stereotactic aspiration of cerebellar abscesses.^{1,3}

Recurrent intraparenchymal abscesses refractory to appropriate antimicrobial therapy and aspiration also are candidates for surgical resection.^{2,6} Certain abscesses, including fungal infections, show a poor response to stereotactic aspiration or medical therapy alone, ultimately requiring surgical excision.¹ Open craniotomy with abscess removal may be preferred for multiloculate abscesses because stereotactic aspiration may fail to drain each pocket of purulent fluid.⁴ Furthermore, an abscess in a location abutting the ventricular system may warrant surgical resection to prevent intraventricular spillage of the abscess contents. In the context of existing ventriculitis, open craniotomy should be performed urgently to débride infected tissue, irrigate the ventricles, and administer intraventricular antibiotics.² Additionally, brainstem abscesses may respond well to open exposure, debulking, and the drainage of purulent material with collapse of the capsule wall under direct visualization.¹³

Disadvantages of Open Craniotomy

Benefits of open craniotomy must be weighed against the disadvantages, including greater invasiveness, potentially longer operative times, greater surgical risk, and greater potential morbidity. Additional factors may disfavor open surgery. For instance, abscesses within stage I of formation (early cerebritis) may lack adequate development to warrant surgical excision. Multiple or deep-seated lesions and those within eloquent cortex may preclude aggressive resection, and serious medical comorbidities may elevate the surgical risk.¹

Endoscopically Assisted Abscess Evacuation

Neuroendoscopy represents an alternative or supplemental approach in many neurosurgical contexts. In the treatment of intraparenchymal abscesses, endoscopy recapitulates the minimally invasive nature of stereotactic aspiration while offering the direct visualization of abscess evacuation and antibiotic lavage (if desired).^{1,18} Direct inspection helps maximize the drainage of purulent fluid and allows the fenestration of septa in multiloculate abscesses.^{1,2,18} Despite sparse literature support showing benefit over other approaches, neuroendoscopy offers an alternative method of brain abscess evacuation deserving further attention.

Multidisciplinary Approaches

Regardless of the surgical approach used, brain abscesses should be managed with a multidisciplinary approach. Frontal

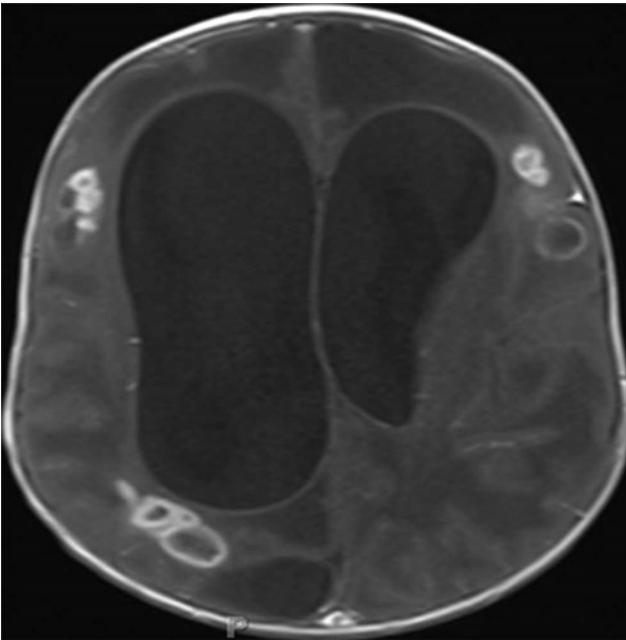

Fig. 79.7 Axial T1-weighted magnetic resonance imaging sequence with gadolinium administration depicting multiple brain abscesses in disparate locations.

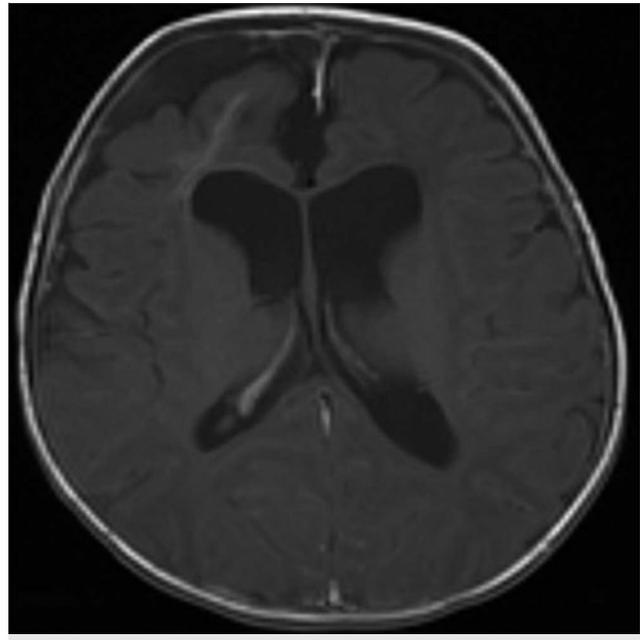

Fig. 79.8 Axial T1-weighted magnetic resonance imaging sequence with gadolinium administration showing evidence of residual contrast enhancement nearly 6 weeks following evacuation of a right frontal brain abscess.

lobe abscesses associated with facial infections or paranasal sinusitis can be managed by pediatric neurosurgeons and by colleagues from head and neck surgery or craniofacial plastic surgery. Similarly, temporal lobe or cerebellar abscesses extending from otitis media or mastoiditis should be approached through a collaborative effort between neurosurgery and otolaryngology.^{1,6} This combined approach may involve a craniotomy and mastoidectomy, either concurrently or at different times.^{3,19} Successful treatment of both the brain abscess and the source of infection decrease the risk for abscess recurrence.¹ Collaboration should extend beyond the surgical specialties to include infectious disease specialists and pediatricians for the safe and effective management of children with brain abscesses.

Antibiotic Therapy

Complementing surgical debulking, antibiotics are an integral component of the treatment of brain abscesses. Initial pharmaceutical selections are based upon the suspected microorganisms involved and the anticipated brain penetration of antimicrobials. Following empiric treatment, the antimicrobial regimen can be tailored based on culture data. The culture data may come from intracranial or extracranial sources, as long as no compelling reasons exist to assume differing identities of the microorganisms involved.

The therapeutic regimen typically entails at least a 4- to 6-week course of intravenous antibiotics, occasionally followed by oral antibiotics for 2 to 3 months.⁴ Some authors argue for a longer duration of intravenous antibiotics, up to 6 to 8 weeks, depending on the clinical scenario.^{2,13} The presence of multiple brain abscesses or immune system deficiency often warrants longer courses of intravenous antibiotics (► Fig. 79.7).¹ The unique setting of ventriculitis alters the treatment

regimen, requiring both systemic and intrathecal antibiotic administration.^{1,2}

Postoperative or Nonoperative Surveillance

Children treated surgically or nonsurgically for intraparenchymal abscesses require close clinical follow-up with neurologic examinations and serial imaging. Weekly or biweekly scans (CT or MR imaging) with contrast administration evaluate the regression or progression of disease.^{4,6} Abscesses that fail to decrease in size after 4 weeks of appropriate antibiotic therapy or that grow after 2 weeks of therapy urge for surgical reconsideration.¹ The bulk of intraparenchymal abscesses typically resolve on imaging by 12 to 16 weeks after the initiation of appropriate therapy. However, complete disappearance of contrast enhancement may require up to 6 months (► Fig. 79.8).¹ Following the discontinuation of antibiotics, serial imaging continues until complete radiographic resolution of all intraparenchymal abscesses.² Inadequate access to medical care limits postoperative surveillance in developing regions or Third World nations.

Treatment Alternatives

Empiric Antibiotic Therapy

Empiric antibiotic therapy is an important, potentially lifesaving component of the treatment of pediatric brain abscesses. However, broad-spectrum agents should not routinely supplant directed antibiotic therapy. Empiric therapy may precede purulent sampling to achieve clinical stability in a deteriorating patient. Preoperative antibiotic initiation often will not preclude microorganism isolation from intracranial sources.^{2,4}

Table 79.3 Examples of empiric antibiotic therapy in pediatric brain abscesses

Source of infection or predisposing condition	Suggested antibiotic regimen	Additional comments
Unknown source or etiology	Third-generation cephalosporin + vancomycin + metronidazole	Broad-spectrum regimen.
Sinusitis, otitis, mastoiditis, cyanotic congenital heart disease	Third-generation cephalosporin + metronidazole	Alternative regimen includes ampicillin/sulbactam, meropenem, or ciprofloxacin; use vancomycin for MRSA.
Penetrating head trauma, ventricular shunt infections, or endocarditis	Third-generation cephalosporin + vancomycin ± metronidazole	Covers MRSA and <i>Staphylococcus epidermidis</i> .
Bacterial meningitis	Third-generation cephalosporin + vancomycin	Covers cephalosporin-resistant <i>Streptococcus pneumoniae</i> .
Neonatal patient	Third-generation cephalosporin + ampicillin	Covers <i>Listeria monocytogenes</i> .
Dental infection	Penicillin + metronidazole	Alternative regimen includes ampicillin/sulbactam.
Immunodeficiency or immunosuppression	Third-generation cephalosporin + vancomycin + metronidazole	Use amphotericin for fungal infections and TMP/SMX for <i>Nocardia</i> infections.
Immunodeficiency (AIDS) and high level of suspicion for tubercular abscesses	Rifampicin + isoniazid + pyrazinamide + ethambutol	

Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; TMP/SMX, trimethoprim/sulfamethoxazole.

Alternatively, antibiotics can be withheld until the acquisition of brain abscess specimens, given patient stability. This practice prevents any potential sterilization of intraoperative cultures.^{1,2}

Broad-spectrum antibiotics should be selected to maximize coverage based on the suspected source of infection (► Table 79.3). Typical regimens include a third-generation cephalosporin with appropriate brain penetration, such as cefotaxime, ceftazidime, or ceftriaxone. The increasing prevalence of methicillin resistance in *S. aureus* and *S. epidermidis* favors vancomycin use in abscesses associated with penetrating head trauma, endocarditis, or ventricular shunts.⁴ Metronidazole joins the antibiotic regimen for abscesses associated with sinus or ear infections or cyanotic congenital heart disease.^{2,4} Neonatal brain abscesses concerning for *Listeria monocytogenes* require the addition of ampicillin.⁴

Antibiotic Therapy with Culture Sampling of Other Infected Sites

Diminutive intraparenchymal abscesses (<2 to 3 cm) with an identified source and suspected microorganism can be treated nonsurgically with appropriate antibiotics.^{1,2,4,6}

Patients who lack neurologic deficits or signs of elevated ICP and who are poor surgical candidates may benefit from medical treatment alone.^{1,2} Alternative culture sources include blood, sputum, and purulent drainage from the ears, sinuses, or contiguous sites of infection.² Disadvantages of the nonsurgical approach include a higher rate of recurrence.¹ The growth of brain abscesses or the appearance of new neurologic deficits despite antimicrobial therapy warrants reconsideration of surgical intervention.

Steroid Therapy

The role of corticosteroids in the treatment of pediatric brain abscesses remains controversial. Although they reduce vasogenic

edema and lowering ICP, steroids adversely affect the treatment of infections.^{2,3} Corticosteroids act as immunosuppressants and decrease antimicrobial penetration into the brain.⁴ These factors limit the use of steroids to clinically unstable children with brain abscesses causing edema and ICP elevation.¹ If initiated, steroids should be continued for a short duration to minimize their disadvantages.

Antiepileptic Agents

Because of mass effect and cortical irritation, brain abscesses carry a risk for propagating seizure activity. Seizures may occur in delayed fashion, with a latency period of up to 3 years.¹ Older reports suggest that only 50% of seizures developing in pediatric patients with intraparenchymal abscesses occur within the first year after diagnosis.¹ In the context of witnessed or documented seizures, anticonvulsants are an integral component of the therapeutic regimen for brain abscesses. However, clinical trial evidence is not available to support the use of prophylactic antiepileptics in children with intraparenchymal abscesses.⁶

Because of the seizure risk associated with brain abscesses and surgical excision, antiepileptic medications are usually recommended prophylactically.¹ Anticonvulsant therapy typically continues for a short duration except in the presence of known seizure activity.⁶ Alternatively, some authors recommend a prolonged duration of prophylactic anticonvulsant therapy.² Drawbacks of antiepileptics include medication side effects and pharmacologic interactions with antibiotics.⁶

79.1.10 Prognostic Factors

The clinical and neurologic status upon presentation significantly affect the prognosis for children with brain abscesses. Mental status or behavioral changes and lethargy correlate with worse outcomes, whereas early detection and intervention

before patient decompensation increase the chances for healthy survival.^{1,2} A delayed presentation is a poor prognostic indicator, especially in developing regions with limited access to care.⁶ The rapid progression of neurologic deficits and a moribund or comatose appearance similarly predict higher rates of morbidity and mortality.

Specific patient or abscess characteristics influence prognosis as well. Younger infants, especially those younger than 1 year, tend to fare worse than older children with brain abscesses.⁴ The coexistence of seizures, hydrocephalus, or meningitis with brain abscesses further worsens the prognosis.¹ Immunocompromised patients typically experience more complicated clinical courses than do their immunocompetent counterparts.⁶ The presence of multiple abscesses or of highly virulent pathogens also portends a worse prognosis.^{1,4} Lesions residing near the ventricles or subarachnoid cisterns are associated with increased risks for poor outcomes. The leakage of abscess contents into the ventricular system or subarachnoid space leads to ventriculitis or fulminant meningitis. The patients exhibit rapid clinical deterioration and may progress to death.^{1,5,6}

79.1.11 Outcomes

Several factors have improved the diagnosis and treatment of brain abscesses over the past 80 years. These include enhanced imaging modalities, stronger antibiotics, advanced surgical techniques, and better culturing methods.^{1,6} The mortality rates for brain abscesses before the discovery of antibiotics ranged between 40 and 60%.¹ Current mortality rates for pediatric brain abscesses overall have declined to 4 to 15%, and those for infratentorial abscesses to 11 to 41%.^{1,3,4}

Although displaying similar trends, the morbidity rates for pediatric brain abscesses remain high, reaching 33% in clinical series.⁴ Common examination findings after treatment include hemiparesis or weakness within one extremity, visual field cuts, and cognitive deficits.^{1,6} Younger children exhibit susceptibility to impaired intellectual development in the setting of brain abscesses.¹ Infratentorial abscesses may lead to delayed hydrocephalus requiring shunt placement, even after successful excision.³ Additionally, supratentorial abscesses may cause delayed or persistent seizure activity.¹

79.1.12 Complications

Several complications are associated with surgical approaches to abscess treatment. Hemorrhage is an important risk with both stereotactic aspiration and open craniotomy. The occurrence of hemorrhage in either operative technique correlates with a worse overall prognosis.⁶ Additional risks for CSF leakage, seizures, and infarction represent important considerations regarding open craniotomy.⁶ With either surgical approach, the entry of abscess contents into the ventricular system or subarachnoid space is a devastating and potentially fatal complication.^{1,6}

79.1.13 Third World Perspectives

The principles of the management of pediatric brain abscesses in Third World countries are similar to the principles followed in developed nations, but with important caveats. Regarding

etiology, chronic otitis media is a predominant cause of intraparenchymal abscesses, along with cyanotic congenital heart disease (e.g., tetralogy of Fallot).^{2,12,20} Chronic suppurative otitis media accounts for up to 30% of patients treated yearly at major tertiary care centers located in developing regions, such as southern India.¹⁹ A retrospective review in Thailand related the high preponderance of pediatric brain abscesses and otogenic infections to low socioeconomic status and inadequate access to medical care.² Resulting delayed or insufficient treatment of otic and other infections subsequently predisposes to brain abscess formation.^{2,12,19} Given these factors, brain abscesses are a frequent neurosurgical pathology in developing nations. For instance, the Korle Bu Teaching Hospital in Ghana reported a 4.8% incidence of brain abscesses (70% occurring in patients younger than 20 years) among neurosurgical admissions over a recent 4-year period.⁷

Most pediatric brain abscesses in developing countries result from the contiguous spread of infection.⁷ Although culture techniques limit microbiological data, the causative pathogens most commonly isolated mirror those in the United States—*Streptococcus* and *Staphylococcus*.⁷ Culture data regarding anaerobes often cannot be obtained, given suboptimal laboratory techniques.⁷ *Bacteroides fragilis* is a predominant anaerobe isolated when culturing techniques are available, similar to findings in developed nations.¹² The rising prevalence of AIDS in developing nations and the limited availability of appropriate treatment regimens increase the risks for opportunistic infections. Regions of endemicity show an increasing frequency of brain abscesses involving *Toxoplasma gondii*, *Nocardia*, *Aspergillus*, and *Candida*.⁷

The diagnosis and treatment paradigms in third world countries match the availability of resources. Because of the expense and paucity of MR imaging scanners, CT with contrast administration is the primary imaging modality implemented. In certain settings, individual patient responsibility for covering the costs of MR imaging further limits its use. Limited access to CT scanners and hospitals with neurosurgical services may delay diagnosis, resulting in worse neurologic status upon presentation.²⁰ When discovered, pediatric brain abscesses in developing nations are often managed with bur hole craniotomy and aspiration, frequently under local anesthesia.⁷ Typically, the lack of sufficient equipment and resources fosters freehand approaches.

Decisions regarding treatment regimens, including parenteral antibiotics, anticonvulsants, and corticosteroids, reflect the trends in developed nations but also respect the limited availability of resources in developing nations. Antibiotic therapy typically lasts for 4 to 6 weeks, with modifications based on the antimicrobials available and the virulence of the pathogens.^{7,19} Given the advent of CT and improved antimicrobial agents, the mortality and morbidity associated with pediatric brain abscesses have significantly declined in developing regions. However, complicating factors like delayed presentation, limited access to care, and unavailability of optimal treatment regimens force these rates to remain high. A retrospective study at Korle Bu Teaching Hospital in Ghana reported a 10.9% mortality rate for brain abscesses in series of patients that included mostly children.⁷ A prospective study in Mumbai, India, from 2001 to 2005 showed a mortality rate of 13.3% for brain abscesses in patients younger than 20 years.¹²

79.2 Encephalitis

79.2.1 Overview

Encephalitis is an inflammatory condition of the brain reflecting infectious or noninfectious etiologies. It causes global or focal neurologic impairment. The term *meningoencephalitis* refers to inclusion of the meninges in the inflammatory process. Many viruses (herpes simplex virus, mumps virus) cause systemic symptoms with rare or benign central nervous system (CNS) involvement, whereas a few viruses (rabies virus, Japanese encephalitis virus) affect the CNS primarily.²¹ Viral encephalitides account for most instances of acute encephalitis, with 1,000 to 2,000 cases yearly (► Table 79.4).^{22,23} Despite advanced diagnostic techniques, the etiology of encephalitis remains

unknown in up to 60% of cases, as shown in the California Encephalitis Project.²²

79.2.2 Clinical Presentation

CNS inflammation occurs via primary infection or secondarily after infection or vaccination. Pathophysiologic mechanisms of acute viral CNS infection include hematogenous dissemination and intraneuronal transmission.^{21,23} Affected patients may experience the classic triad of fever, headache, and altered mental status.^{21,22} Additional global or focal neurologic deficits often correlate with specific viral pathogens (► Table 79.5). Neurologic findings may include changes in speech, executive function, behavior, or level of consciousness; deficits in cranial nerves or strength; and seizures.^{21,22}

Table 79.4 Examples of acute viral encephalitis occurring in the pediatric population

Viral families causing encephalitis	Current or proposed treatment or prevention
Bunyavirus encephalitis La Crosse encephalitis virus California serogroup viruses Toscana virus	Ribavirin (intravenous)
Flavivirus encephalitis Dengue virus Japanese encephalitis virus Powassan encephalitis virus St. Louis encephalitis virus Tick-borne encephalitis viruses West Nile virus	Vaccine available Interferon- α -2b Vaccine available (Europe) Interferon- α , intravenous immunoglobulin
Herpesvirus encephalitis Cytomegalovirus Epstein-Barr virus Herpes simplex viruses 1 and 2 Human herpesvirus 6 Varicella-zoster virus	Ganciclovir, foscarnet, or cidofovir Acyclovir Ganciclovir, foscarnet, or cidofovir; vaccine available Acyclovir, steroids; vaccine available
Orthomyxovirus encephalitis Influenza A virus, influenza B virus	Vaccine available
Papovavirus encephalitis JC virus	
Paramyxovirus encephalitis Rubeola virus (measles virus) Mumps virus Nipah virus	Vaccine available Vaccine available Ribavirin (intravenous)
Picornavirus encephalitis Enterovirus 71 Other enteroviruses Poliovirus	Vaccine available
Reovirus encephalitis Colorado tick fever virus	Ribavirin (experimental)
Retrovirus encephalitis Human immunodeficiency virus	Antiretroviral therapy
Rhabdovirus encephalitis Chandipura virus Rabies virus	Ribavirin (intravenous), iatrogenic coma; vaccine available
Togavirus encephalitis Eastern equine encephalitis virus Venezuelan equine encephalitis virus Western equine encephalitis virus	

Table 79.5 Common clinical findings associated with viral encephalitides

Viral etiology	Unique clinical findings	Patient characteristics or mechanism of exposure
Chandipura virus	Seizures, focal neurologic deficits	Children in southern India
Cytomegalovirus	Hearing loss, seizures, mental retardation, developmental delay	Congenital infection, immunocompromised
Eastern equine encephalitis virus	Seizures, fulminant course to coma; high mortality rate	More common in older adults than in children
Enterovirus	Flaccid paralysis	
Herpes simplex virus	Seizures, focal neurologic deficit; temporal lobe location	HSV-2 in neonates, HSV-1 in infants and children
Japanese encephalitis virus	Seizures, tremor, rigidity, masklike facies; flaccid paralysis (uncommon)	Mosquito bite transmission
JC virus	Progressive multifocal leukoencephalopathy (PML)	Immunocompromised
La Crosse virus	Focal seizures, weakness, paralysis, delirium, coma	More common in children than in adults, mosquito bite transmission
Rubeola virus (measles virus)	Subacute sclerosing panencephalitis (SSPE), cognitive decline, incoordination	Immunocompromised
Nipah virus	Brainstem involvement, autonomic instability, hypotonia; small-vessel vasculitis within cerebral white matter	Pig farm workers, fruit bat exposure; mostly in Bangladesh and India
Poliovirus	Flaccid paralysis	Lack of vaccination, immunocompromised
Powassan virus	Memory deficits, confusion, seizures; hippocampal predilection	Tick bite exposure; northeastern United States and Canada
Rabies virus	Lability, behavioral changes, autonomic abnormalities	Animal bite or bat exposure
Tick-borne virus	Flaccid paralysis, transverse myelitis	Tick bite exposure
Varicella-zoster virus	Cerebellitis, temporal lobe deficits	Immunocompromised
West Nile virus	Flaccid paralysis, tremors	Mosquito bite transmission; serious sequelae more often in elderly or immunocompromised
Western equine encephalitis virus	Seizures	Mostly infants affected

79.2.3 Diagnosis

MR imaging, CSF analysis, and clinical history are the primary diagnostic tools in acute encephalitis. The clinical history focuses on age, symptoms, exposures, travel, vaccination history, immune status, geography, and seasonal timing.²³ Key distinguishing features that favor encephalitis over meningitis include altered sensorium progressing to behavioral or cognitive changes, coma, seizures, or focal deficits.²³ The examination incorporates a neurologic assessment and general evaluation for skin rashes and sites of exposure.

Imaging findings vary among the acute viral encephalitides. Nonspecific MR imaging findings include T2 hyperintense lesions with variable mass effect and edema.²³ Classic MR imaging findings include temporal or sylvian fissure hemorrhagic inflammation in herpes simplex virus (HSV) encephalitis and diffuse white matter lesions in progressive multifocal leukoencephalopathy (PML; associated with JC virus).²³ With gadolinium contrast enhancement, the lesions may appear diffuse and involve the meninges.²³ Other para-infectious encephalitides exhibit recognizable MR imaging characteristics, including asymmetric white matter lesions in acute disseminated encephalomyelitis (ADEM) and symmetric T2 hyperintense periventricular white matter lesions in acute necrotizing encephalopathy

(ANE).²² Electroencephalography (EEG) is another diagnostic modality potentially useful in acute encephalitis. Although diffuse abnormalities appear in various encephalitides, focal aberrant activity may be seen in HSV encephalitis and subacute sclerosing panencephalitis (SSPE) caused by measles virus.^{22,24}

CSF analysis includes Gram stain, cell counts, molecular profiles, culture, and polymerase chain reaction (PCR). Although the cell count, glucose level, or protein level may appear unremarkable, many viral encephalitides cause mild elevations of CSF monocytes or protein.²¹ Depressed CSF glucose levels may indicate bacterial or HSV infection.²² Routine CSF viral PCR studies search for HSV, enterovirus, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV) infection. With appropriate clinical suspicion, additional CSF studies include immunoglobulin M (IgM) analysis for Japanese encephalitis virus, VZV, West Nile virus (WNV), or *Borrelia* antibodies.²²

79.2.4 Treatment

Empiric therapy is directed at potential causes of both bacterial meningitis and acute viral encephalitis. Among the few effective antiviral agents, acyclovir is the primary empiric agent used in children.^{21,22} A typical broad-spectrum regimen includes acyclovir, vancomycin, and a third-generation cephalosporin (plus

ampicillin in neonates).²² Antibiotics should be tailored and modified upon return of the CSF and other diagnostic studies. Following empiric therapy, supportive care and close monitoring are the primary management strategies for viral encephalitis lacking definitive treatment options. Measures to control elevated ICP can reduce the primary mortality factor in fulminant viral encephalitis.²⁵

79.2.5 Prevention

For several viral encephalitis, exposure control and vaccination are the primary methods to combat infection. Vaccines are readily available for Japanese encephalitis, polio, rabies, influenza A and B, mumps, and measles viruses.^{21,22} Before major immunization efforts were undertaken for children in the United States, measles virus and mumps virus were the two primary causes of acute encephalitis and post-infectious encephalitis (SSPE).²² However, vaccines have nearly eradicated or significantly reduced the prevalence of these and other viral encephalitis. Vector control and the avoidance of animal exposure are helpful adjuncts for the prevention of many viral encephalitis.^{21,26}

79.2.6 Selected Acute Viral Encephalitis

Herpes Simplex Virus Encephalitis

Although it is a frequent cause of systemic illness, HSV infiltrates the CNS uncommonly beyond infancy.²¹ However, because of the widespread nature of HSV infection, this virus accounts for most cases of non-epidemic acute encephalitis in the United States, with an incidence between 1 in 250,000 and 1 in 500,000.^{21,27} Approximately one-third of cases of HSV encephalitis occur in pediatric patients.²⁴ Furthermore, the frequency of CNS involvement in infantile HSV infection reaches nearly 50%.²⁷ HSV encephalitis exhibits Cowdry type A intranuclear inclusions histologically and shows positive results on PCR analysis of the CSF.^{21,24}

The specific variant of HSV encephalitis differs between neonates and older children. Neonatal patients acquire HSV-2 infection primarily during passage through an infected maternal birth canal.²⁷ Infection spreads hematogenously and may result in diffuse areas of hemorrhagic necrosis and encephalomalacia.^{24,27} In contrast, infants and older children with HSV-1 encephalitis show unilateral temporal involvement that ultimately spreads to involve both temporal lobes.²¹ The mechanism of disease spread in HSV-1 infection involves retrograde transport along axons.^{23,24} Because of its predilection for the temporal lobe, HSV encephalitis may result in clinical findings of aphasia, seizures, or other focal deficits.^{21,24} Neonates with encephalitis due to HSV-2 infection have a worse outcome than those with HSV-1 infection.²¹

In contrast to many other encephalitis, HSV encephalitis responds favorably to direct therapy with acyclovir. Despite this effective treatment, pediatric mortality and morbidity remain high. The age-independent mortality of patients with treated HSV encephalitis reaches 28%, and children have a worse prognosis.²¹ Newer treatment regimens involving longer durations

of therapy (21 days) and higher doses of acyclovir (60 mg/kg per day as opposed to the standard 30 mg/kg per day) have improved outcomes in neonatal HSV encephalitis.^{23,24}

Enterovirus Encephalitis

Enteroviral encephalitis typically exhibits a low level of morbidity, with cognitive changes, lethargy, and seizures.²³ In contrast, a Taiwanese 1998 epidemic associated with enterovirus 71 had higher rates of pediatric morbidity and mortality (19% in children younger than 5 years).²¹ Exhibiting preferential brainstem involvement, enterovirus 71 may induce tremors, ataxia, cranial nerve deficits, or neurogenic shock. Excluding the polio vaccine, no definitive antimicrobial regimens or vaccines exist to combat enteroviral encephalitis.²¹

West Nile Virus Encephalitis

Emerging in the 1990s and reaching North America by 1999, a more virulent subtype of WNV has caused several outbreaks owing to its broad host (birds) and expansive vector (*Culex* mosquitoes).^{21,22,28} However, only 1 to 2% of WNV infections result in acute encephalitis.^{22,26,28} Furthermore, children account for a minority of infected patients (<10%) and develop neurologic sequelae less frequently than adults.^{22,26,28} Neurologic deficits in WNV encephalitis include acute flaccid paralysis, disorientation, stupor, dyskinesias, and tremors.^{21,22,26,28} Proposed treatment regimens include interferon- α and intravenous immunoglobulin, but no direct antiviral therapies or vaccines exist.^{21,26}

La Crosse Encephalitis

La Crosse encephalitis virus affects primarily school-age children and is the most common endemic cause of acute viral encephalitis in America since the 1960s, accounting for 30 to 180 cases yearly.²⁵ Pediatric patients may present with focal seizures, weakness, or paralysis and progress from delirium or lethargy to coma.^{21,25} Mortality rates for La Crosse encephalitis fall below those of other viral encephalitis, while morbidity rates reach 10 to 15%.²¹ Clinical series and case reports describe the use of intravenous ribavirin as therapy for La Crosse virus encephalitis.^{22,25}

Japanese Encephalitis

Transmitted through *Culex* mosquitoes, Japanese encephalitis virus mainly affects children in regions of China, southeastern Asia, India, Pakistan, eastern Russia, the Philippines, and Australia where it is endemic.^{21,29} Although fewer than 1% of infections result in encephalitis, pediatric patients may develop altered mental status, seizures, tremors, rigidity, and acute flaccid paralysis.^{21,29} MR imaging findings include mixed-intensity lesions within the diencephalon and mesencephalon, and CSF analysis may detect IgM antibodies.²¹ The prognosis for children with Japanese encephalitis remains poor, with mortality and neurologic morbidity rates reaching 30% and 50%, respectively.²⁹ Management involves pre-exposure vaccination and post-exposure supportive care.²¹

Rabies Encephalitis

Exhibiting high neurotropism, the rabies virus spreads intraneuronally to preferentially infect neurons of the limbic system and cause isolated CNS infection.^{21,22} Primary modes of human inoculation include exposure to bats and animal bites, especially bites from infected dogs in developing nations.²¹ Following an incubation period typically ranging from 20 to 60 days, neurologic symptoms may progress from lability, behavioral changes, and weakness to coma or death.^{21,22}

Salivary reverse-transcriptase PCR aids the diagnosis, and histology portrays intracytoplasmic Negri bodies.²¹ Without intervention, the mortality of rabies encephalitis reaches 100%. Management involves prevention, pre-exposure vaccination, and post-exposure vaccination with the rabies immunoglobulin and vaccine.²¹

Tick-Borne Encephalitides

Tick-borne encephalopathy results from viral or bacterial etiologies and includes tick-borne encephalitis, Lyme neuroborreliosis, and Rocky Mountain spotted fever. Caused by a member of the flavivirus family, tick-borne encephalitis exhibits a milder course in children than in adults, with occasional residual cognitive impairment and a low mortality rate.³⁰ Although no direct treatment of tick-borne encephalitis exists, management involves active immunization with vaccines (in Europe) and prevention through the avoidance of tick bites or early tick removal.³⁰ Post-exposure prophylaxis with immunoglobulin G (IgG) is contraindicated in children younger than 15 years because of the potential induction of a severe (even fatal) clinical course.³⁰

Members of the bacterial spirochete family, *Borrelia* species cause Lyme borreliosis. An erythema migrans rash develops at the tick exposure site, and the hematogenous spread of spirochetes may induce neuroborreliosis 4 to 8 weeks later, signified by meningoencephalitis, radiculitis, or facial nerve palsy in children.³⁰ Treatment for neuroborreliosis includes doxycycline (contraindicated in children younger than 8 years), amoxicillin, ceftriaxone, or penicillin G.³⁰ As a less common cause of bacterial encephalitis, Rocky Mountain spotted fever may induce behavioral changes, delirium, seizures, or coma following the presentation of a macular hemorrhagic rash.³⁰ The sequelae of Rocky Mountain spotted fever in children can be treated with doxycycline or levofloxacin.³⁰

Acute Disseminated Encephalomyelitis

With characteristics similar to those of multiple sclerosis and neuromyelitis optica, ADEM is a demyelinating disease that follows an infection, vaccination, or nonspecific illness. Although it is the most common white matter disease in children, ADEM occurs infrequently, with an incidence of 0.4 per 100,000.²³ A large series of pediatric ADEM cases in 2003 reported a median age at onset of nearly 7 years, with more than 50% of children having had a preceding illness or vaccination.²² This autoimmune inflammatory condition affects the CNS white matter bilaterally and often asymmetrically.^{22,23} With nonspecific CSF findings of lymphocytic pleocytosis and elevated protein, the diagnosis of ADEM relies upon MR imaging and clinical history.²³ Neurologic symptoms include motor deficits, ataxia,

seizures, visual or speech abnormalities, impaired cognition, behavioral changes, and autonomic dysregulation.^{22,23} The diagnosis must be differentiated from multiple sclerosis, which requires a multiphasic presentation. First-line therapy for ADEM involves intravenous steroids (corticosteroids for 3 to 5 days or dexamethasone for 10 days), followed by an oral prednisone taper over 14 to 21 days (or longer).^{22,23} Children with a poor response to steroids may undergo immunoglobulin therapy or plasma exchange.²²

Pearls

- Pediatric brain abscesses require early diagnosis and intervention to minimize patient morbidity and mortality. Children presenting with fever, headaches, altered mental status, and coexisting sites of infection should elevate clinical suspicion.
- Frequently contraindicated because of mass effect, CSF acquisition via lumbar puncture is often of little diagnostic utility in brain abscesses lacking ventricular or subarachnoid extension.
- Broad-spectrum antibiotics should be initiated early in an unstable patient. However, empiric agents should never replace culture-directed therapy.
- Stereotactic aspiration offers a minimally invasive approach to acquiring culture data and reducing mass effect. The rate of abscess recurrence is typically higher with this approach than with open excision.
- Open craniotomy for abscess resection allows greater decompression and reduction of mass effect, but with greater surgical risk and morbidity.
- Acute deterioration in a pediatric patient with a brain abscess may signal intraventricular rupture or subarachnoid dissemination of the abscess contents. Ensuing ventriculitis or fulminant meningitis may be fatal and requires urgent intervention.
- Acute viral encephalitis often presents with fever, altered mental status, focal neurologic deficit, and/or seizures.
- Few antiviral agents besides acyclovir are available to combat acute encephalitis. Many treatment regimens rely on post-exposure vaccination or supportive care.
- Pre-exposure vaccination, vector control, and other preventive measures are successful strategies to reduce the occurrence of acute infectious encephalitis.

80 Tuberculosis, Parasitic Infestations, and Fungal Infections

Graham Fieggen and Llewellyn C. Padayachy

Although tuberculosis, fungal infections, and parasitic infestations of the nervous system have declined in importance in developed countries over the course of the 20th century, they have received renewed attention in recent years because of their impact on vulnerable groups, such as persons infected with the human immunodeficiency virus (HIV) or receiving immunosuppressive treatment. The increased migration of people in the era of globalization has also played a significant role because these infections remain important causes of neurologic disease in developing countries. Patients may present either with focal lesions that require surgical management or with widespread central nervous system (CNS) disease, such as meningitis, which in this setting is often complicated by hydrocephalus.

80.1 Tuberculosis

The tide appears to be turning against tuberculosis (TB) once again; although there were 8 million new cases worldwide in 2010, with 1.1 million deaths in HIV-negative patients and 350,000 deaths from HIV-associated TB, there has been a fall in the absolute number of cases since 2006, sustaining hope that the Millennium Development Goal of falling TB incidence rates will be achieved by 2015.¹ The number of new cases in 2011 fell among both U.S.-born and foreign-born persons in the United States.²

TB is caused by infection with an aerobic, nonmotile, rod-shaped bacterium readily identified on Ziehl-Neelsen (acid-fast bacillus) stain, almost invariably *Mycobacterium tuberculosis*. There is an important distinction between asymptomatic infection, which is common, and disease, which occurs in a minority of cases.

Pulmonary infection results from the inhalation of aerosolized droplets; phagocytes carry bacilli from the alveoli to regional lymph nodes, which enlarge and form the so-called primary complex with the lung lesion. Lymphatic and hematogenous dissemination to other organs also occurs in the first few weeks, which in its most severe form presents as miliary TB. Macrophages are the primary cells infected by *M. tuberculosis*, and mycobacterial antigens trigger T helper cells to produce interferon- γ , which activates the macrophages to become bactericidal. Activated macrophages secrete tumor necrosis factor (TNF) and produce the epithelioid cells and giant cells typical of tuberculous granulomas.³

In approximately 95% of cases, infection is controlled by this activation of cell-mediated immunity in the host, but in some patients, the lung lesion gives rise to progressive pulmonary disease or extrapulmonary spread, resulting in systemic miliary TB or isolated TB in any of the organs seeded.³ Secondary TB may follow many years later as a consequence of reduced host immunity, with reactivation of a latent focus or exogenous reinfection. CNS involvement occurs in approximately 1% of persons with TB⁴ and takes the form of tuberculous meningitis (TBM),

focal parenchymal lesions, such as tuberculomas or tuberculous abscesses, or tuberculous osteomyelitis, either of the skull or vertebrae (Pott disease, discussed in Chapter 81).

80.1.1 Tuberculous Meningitis

TBM is the most lethal form of systemic tuberculosis, and in some parts of the world it is the most common form of bacterial meningitis; in sub-Saharan Africa, this has largely happened on the back of the HIV pandemic.^{5,6} In general, TBM is typically a disease of young children in countries with a high incidence of the disease, whereas in countries with a low incidence, it is seen more often in adults, arising from reactivation of a dormant focus.⁵

Rich and McCordock proposed that mycobacteria spread via the blood to the CNS, where a parenchymal or subpial focus develops and the cerebrospinal fluid (CSF) space is entered when the so-called Rich focus ruptures into the subarachnoid space.⁷ Other possible routes into the CSF include rupture of a focus in the choroid plexus or elsewhere in the ventricle, spread from a contiguous bony structure, and delayed rupture of a previously controlled caseous focus. The characteristic feature is a thick, gelatinous exudate in the basal cisterns, common consequences of which are hydrocephalus and cerebrovascular involvement; both of these contribute to ischemia, raised intracranial pressure (ICP), and parenchymal injury.^{8,9}

More than half of all cases may have infarcts on magnetic resonance (MR) imaging or at autopsy, and although vasospasm and external compression of the basal arteries of the circle of Willis and their perforators may play a role, histologic studies show infiltrative, proliferative, and necrotizing changes as well as thrombosis in arteries and veins.¹⁰ Infarcts are found in the diencephalon or the cortex¹¹⁻¹³ and may develop even after treatment has been started and the ICP is normalized.¹⁴ Stroke in TBM occurs in up to 56% of cases, with an even higher prevalence in childhood.^{15,16} Vascular complications in TBM are therefore common and often fatal, making ischemia the most important reason that patients with tuberculous hydrocephalus (TBH) fail to improve clinically or even deteriorate further despite aggressive medical treatment and the early treatment of hydrocephalus.¹⁷

Hydrocephalus is present in 70% of TBM cases¹⁸ and is due mainly to blockage of the basal cisterns by tuberculous exudate in the acute stage and adhesive leptomeningitis in the chronic stage. Although typically communicating hydrocephalus develops, noncommunicating hydrocephalus is reported to occur in approximately 17% of cases as a result of obstruction at the outlet foramina of the fourth ventricle or the aqueduct by meningeal exudate, edema, or a tuberculoma,¹² or a combination of these factors.

The diagnosis of TBM is made in the appropriate clinical context on the basis of CSF analysis results supported by appropriate imaging findings. This is more easily said than done, and clinical research in this area has been hampered by the lack of

standardized diagnostic criteria.¹⁹ Perhaps the greatest challenge is to make the diagnosis early, which is difficult because of the nonspecific early features of TBM; a review of 554 pediatric cases seen over a 20-year period found that 91% of patients had poor weight gain or weight loss, and this may be an important early clue.¹⁸ The prevalence of the disease in the community determines the degree of clinical suspicion. The diagnosis is suggested by a history of a TB contact and a positive tuberculin skin test or Mantoux test result; the chest X-ray may show findings typical of pulmonary TB, and the organism may be identified or cultured from sputum or gastric washings. New molecular diagnostic tools, such as the fully automated amplification system Xpert MTB/RIF, have been introduced into clinical practice and are being validated for CNS disease, but major challenges in scale-up exist in countries where the need is greatest.²⁰

The gold standard for the initial diagnosis of TBM is the demonstration of acid-fast bacilli under the microscope, but the yield is low unless large volumes of CSF are collected. Microscopy typically shows pleocytosis, with a cell count seldom greater than 500/mm³. Lymphocytes predominate, although polymorphonuclear leukocytes may on occasion be more numerous, particularly in the early phase of the disease. Typically, the CSF glucose is low and the protein is elevated. *M. tuberculosis* is particularly slow-growing, so culture plays no role in the initial diagnosis and management of the disease, but it becomes important should one not see an adequate clinical response, because multidrug resistance or extended drug resistance should be considered.

The typical appearance of TBM on computed tomography (CT) is often described as a triad of contrast enhancement of the basal meninges with hydrocephalus and infarcts²¹ (► Fig. 80.1). Hyperdensity may be noted in the basal cisterns before the administration of contrast, and this represents the cisternal exudate.²² Low densities related to cerebral ischemia are common, particularly in the vascular territory of the middle cerebral artery, involving the lenticulostriate and thalamoperforating vessels in the so-called TB zone adjacent to the basal ganglia.^{15,17} Occasionally, accompanying tuberculomas or tuberculous abscesses may be noted. It has been shown that there is no direct correlation between ventricular size and ICP in TBM.²³

Antituberculous medication comprises an initial intensive phase with four drugs; isoniazid (INH), rifampicin (RIF), and pyrazinamide (PZA) are recommended together with either streptomycin, ethambutol, or ethionamide. Some authors advocate treatment with four drugs for 6 months,¹⁸ whereas others prefer 9 to 12 months.^{24–26} Pyridoxine should be prescribed with INH to prevent peripheral neuropathy. The emergence of strains resistant to two front-line drugs, INH and RIF (multi-drug-resistant TB), has been followed by the emergence of extended drug-resistant TB.⁶

Steroids are of proven benefit in reducing mortality and possibly morbidity in children.^{27,28} Hyponatremia is commonly seen and may be due to either the syndrome of inappropriate antidiuretic hormone (SIADH) secretion or cerebral salt wasting. Distinction between the two causes may be difficult; fluid restriction must be avoided unless there is clear evidence of fluid overload, and sodium replacement with hypertonic saline may be indicated.⁹ Follow-up imaging is of value in detecting complications, such as hydrocephalus and infarcts.²⁹

Fig. 80.1 Tuberculous meningitis. Axial computed tomographic scan following the intravenous administration of contrast showing hydrocephalus, low-density lesions in the basal ganglia, and leptomeningeal enhancement in the basal cisterns.

The optimal management of TBH is controversial with respect to the indications for surgery and the choice of operation, with most institutions developing their own treatment algorithms.³⁰ A logical point of departure is determining whether the patient has communicating hydrocephalus or noncommunicating hydrocephalus. Because axial CT is unreliable in this respect,³² a number of authors have advocated the use of air encephalography to demonstrate communication between the ventricular and subarachnoid CSF.^{18,33} This must be done under carefully controlled circumstances, with the option of immediate surgical intervention in cases of noncommunicating hydrocephalus.

Nonsurgical treatment will be effective in about 70% of children with communicating hydrocephalus. It entails the use of diuretics, such as acetazolamide (50 mg/kg) and furosemide,¹⁸ and/or repeated lumbar punctures.³⁴ Those who fail medical management will require a shunt. Bhagwati³⁵ reported the use of ventriculoatrial shunts in TBH in 1971, but ventriculoperitoneal shunts soon became the preferred option,³⁶ although various authors have reported a high rate of complications.^{37,38} Because some patients do not respond despite control of hydrocephalus, some authors advocate a selective approach, inserting an external ventricular drain as a temporary measure and then placing a shunt in those who respond.^{39,40}

Endoscopic third ventriculostomy (ETV) as a treatment option for noncommunicating hydrocephalus in acute TBH was first reported in 2003,⁴¹ and subsequent analysis of the experience at this center disclosed a success rate of about 60% in cases in which the procedure was successfully completed.³¹ ETV in

this setting is technically challenging because the floor of the third ventricle is usually thickened, and copious fibrinous exudate in the basal cisterns makes identification of the cisternal space and the major vessels difficult. Some authors report greater success with ETV in chronic TBH when the acute exudate has resolved.^{30,42}

With appropriate antituberculous therapy, the majority of children with TBM survive, but the long-term neurologic, psychometric, and behavioral outcome is often poor. A wide range of outcomes has been reported,¹⁸ with death in 7 to 57%, neurologic sequelae in 13 to 75%, and normal outcome in only 11 to 61%. There is an urgent need for improved diagnostic tools that will enable earlier diagnosis, as well as biological markers that reflect extent of disease and response to therapy.

80.1.2 Tuberculoma

Tuberculomas are discrete lesions that represent focal infection; multiple lesions may be present in half of all cases⁴³ and may be seen with or without concomitant TBM. In the preantibiotic era, tuberculomas accounted for 3.6 to 50.8% of intracranial masses encountered by neurosurgeons,⁴⁴ but these lesions have declined in neurosurgical importance since the advent of effective antituberculous drugs and modern imaging.

Tuberculomas can occur anywhere in the brain but are rare in the spinal cord.⁴⁵ They are found more commonly in children, in whom they have a predilection for the cerebellum. A tuberculoma most commonly comes to medical attention either as a large lesion with mass effect causing neurologic symptoms, hydrocephalus, or diagnostic uncertainty or as a smaller supratentorial lesion causing seizures.

A mature tuberculoma is typically a well-defined, lobulated, avascular mass with a yellowish, gritty, caseating central core surrounded by firm collagenous tissue or softer pink granulation tissue.⁴⁴ The wall tends to be thicker and more crenated or nodular than those of a typical bacterial abscess,⁴⁶ and the mass may be attached to adjacent dura, leading to the mistaken intraoperative impression of a meningioma. Immature lesions may consist of multiple small tubercles, some with caseating or cystic centers, and there may be intense white matter edema.⁴⁴ Microscopically, a central zone of necrosis is surrounded by tuberculous granulation tissue comprising epithelioid cells, Langerhans giant cells, lymphocytes, polymorphonuclear cells, and plasma cells; acid-fast bacilli are often identified.

The typical imaging appearance is a lesion that is isodense or hyperdense on CT and is isointense on T1 and hypointense on T2 MR imaging; T2 hypointensity is noteworthy because this is seldom found in other intracranial masses.^{47,48} Studies correlating the imaging appearance with pathology suggest that the most common type of necrosis seen in CNS tuberculomas is not caseous but gummatous necrosis, in which inflammatory granulation tissue undergoes ischemic necrosis. By contrast, caseous necrosis is hypodense or isodense on CT and is isointense or hypointense on T1 and hyperintense on T2 MR imaging (similar to a bacterial abscess).⁴⁶ The lesion enhances avidly with contrast, showing a dense unbroken ring of enhancement, in some cases an enhancing nodule or disk, or a combination of rings and disks, which may coalesce.⁴³

The clinical presentation is similar to that of other slowly evolving intracranial space-occupying lesions. Features that

may point to the diagnosis are constitutional symptoms (e.g., weight loss, fever, malaise); a history of TB or a TB contact; a high frequency of seizures, even with a cerebellar lesion; and a positive Mantoux test.⁴³ Young children may have macrocrania.

The old clinical observation that patients with tuberculomas are often better nourished than those with TBM may point to better immunologic function. Small lesions that present with seizures alone may be difficult to distinguish from cysticercal granulomas, and in the absence of active tuberculosis elsewhere, they may not require treatment other than anticonvulsants. This is discussed in more detail later in the chapter. Larger lesions should be treated with the standard four-drug regimen of INH, RIF, PZA, and either ethionamide or ethambutol for up to 4 months, followed by two drugs for up to 18 months or longer, depending on clinical and radiologic response.⁴⁹ Steroids may be indicated should there be significant edema, and anticonvulsants are often required.

Most tuberculomas resolve with medical treatment alone, and surgery is indicated only if the lesion causes life-threatening raised ICP or fails to respond to medical treatment, or if the diagnosis is in doubt. A clear plane of cleavage is typically found between the lesion and the brain,⁵⁰ and complete excision may be possible for lesions that are small enough or superficial (► Fig. 80.2). Larger lesions may require piecemeal removal, but this does carry a risk for inciting meningitis.⁴⁴ Stereotactic aspiration⁵¹ has been reported for deep-seated lesions, but this may be difficult owing to the firm nature of the lesions.⁴³ Hydrocephalus due to a posterior fossa lesion may be very effectively managed with an ETV (► Fig. 80.3). Despite appropriate and effective drug therapy, tuberculomas may sometimes enlarge,⁵² a phenomenon termed *paradoxical expansion*, but eventually most do respond.

80.1.3 Other Tuberculous Lesions

Tuberculous Abscess

Tuberculous abscess is an encapsulation of pus containing viable tubercle bacilli and must be distinguished from a tuberculoma with central liquefaction.⁵³ Tuberculous abscesses may be refractory to treatment despite repeated surgical drainage, and in one small series, the addition of thalidomide to the antituberculous treatment regimen resulted in significant improvement.⁵⁴ This effect is mediated via cytokines, such as TNF- α .⁴ Another immunologically mediated condition is the immune reconstitution inflammatory syndrome (IRIS) seen in HIV-infected patients following the commencement of combination antiretroviral therapy (cART).⁵⁵

Tuberculous Osteitis

Tuberculosis may on rare occasions involve the bones of the skull base or the vault (the lesions are often referred to as caries).⁵⁶ Tuberculous osteitis may present as a fluctuant scalp swelling (cold abscess) or as an ulcerated lesion that is easily mistaken for an infected scalp laceration. If the correct diagnosis is made, surgery may not be indicated because the lesion will usually respond to antituberculous drugs.

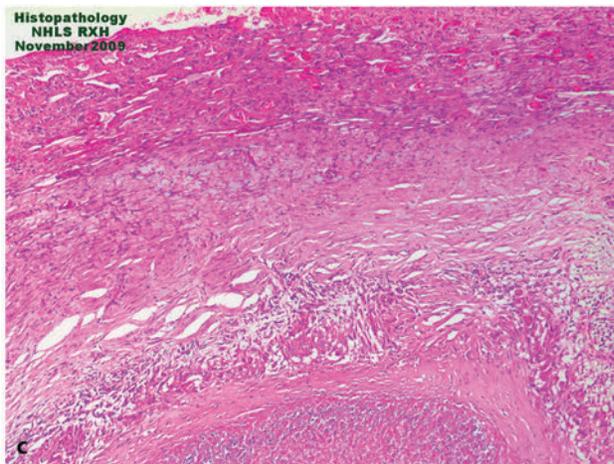

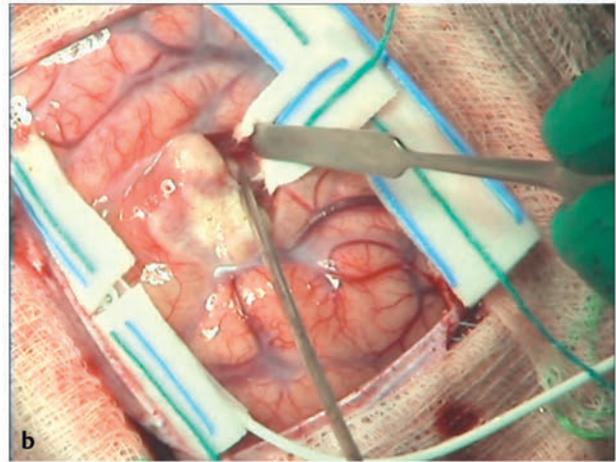

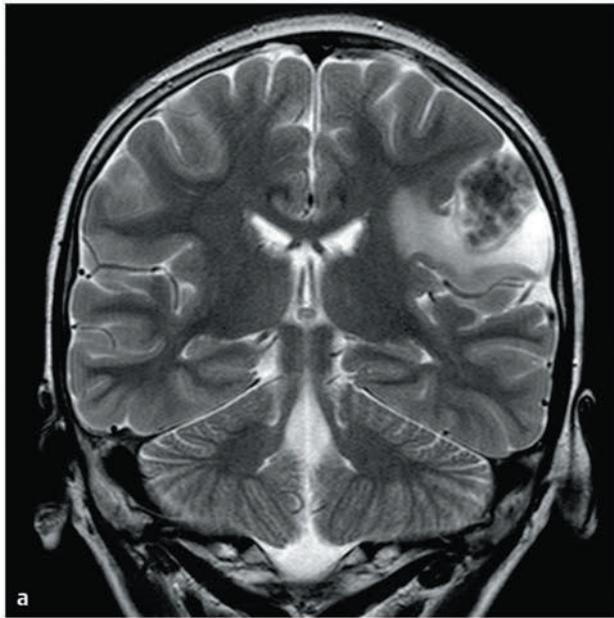

Fig. 80.2 Cortical tuberculoma. (a) A 12-year-old HIV-positive patient with a cortical lesion that did not respond despite 12 months of antituberculous treatment. Initial magnetic resonance image shows a T2 hypointense, inhomogeneous cortical tuberculoma in the left parietal lobe. (b) At surgery, the lesion was easily separated from the surrounding brain. (c) Histology showed typical features of a tuberculous granuloma.

Solitary Small Enhancing Cerebral Lesions

The small solitary cerebral lesion in a patient with seizures remains a subject of considerable interest. Although the differential diagnosis for a solitary cerebral enhancing lesion is extensive, the two most common inflammatory diagnoses, particularly in regions where they are endemic, remain tuberculosis and cysticercosis.⁵⁷ The relevant clinical and imaging features of these two conditions are summarized in ► Table 80.1. An Indian series comparing the features of these two inflammatory lesions listed some of the differentiating characteristics.⁵⁷ Active tuberculosis requires the commencement of antituberculous medication, whereas cysticercosis is usually self-limiting, requiring only single-agent antiepileptic medication with regular clinical and imaging follow-up to monitor resolution of the lesion.^{58,59}

80.2 Parasitic Infestations

Parasitic infestation of the CNS affects millions of people, mostly in the developing world, where poverty and related conditions prevail, although a change in the geographic distribution of these diseases has become more evident in the era of globalization. Parasitic infestations can be broadly classified as protozoan (caused by single-celled organisms) and metazoan/helminthic (caused by complex, multicellular organisms).

80.2.1 Cysticercosis

Cysticercosis was initially described by the ancient Greeks, who identified cysticerci (meaning “bladder tails”) in pork.⁶⁰ Neurocysticercosis results from infestation of the CNS by larvae of the helminthic tapeworm *Taenia solium*. Cysticercosis is the most

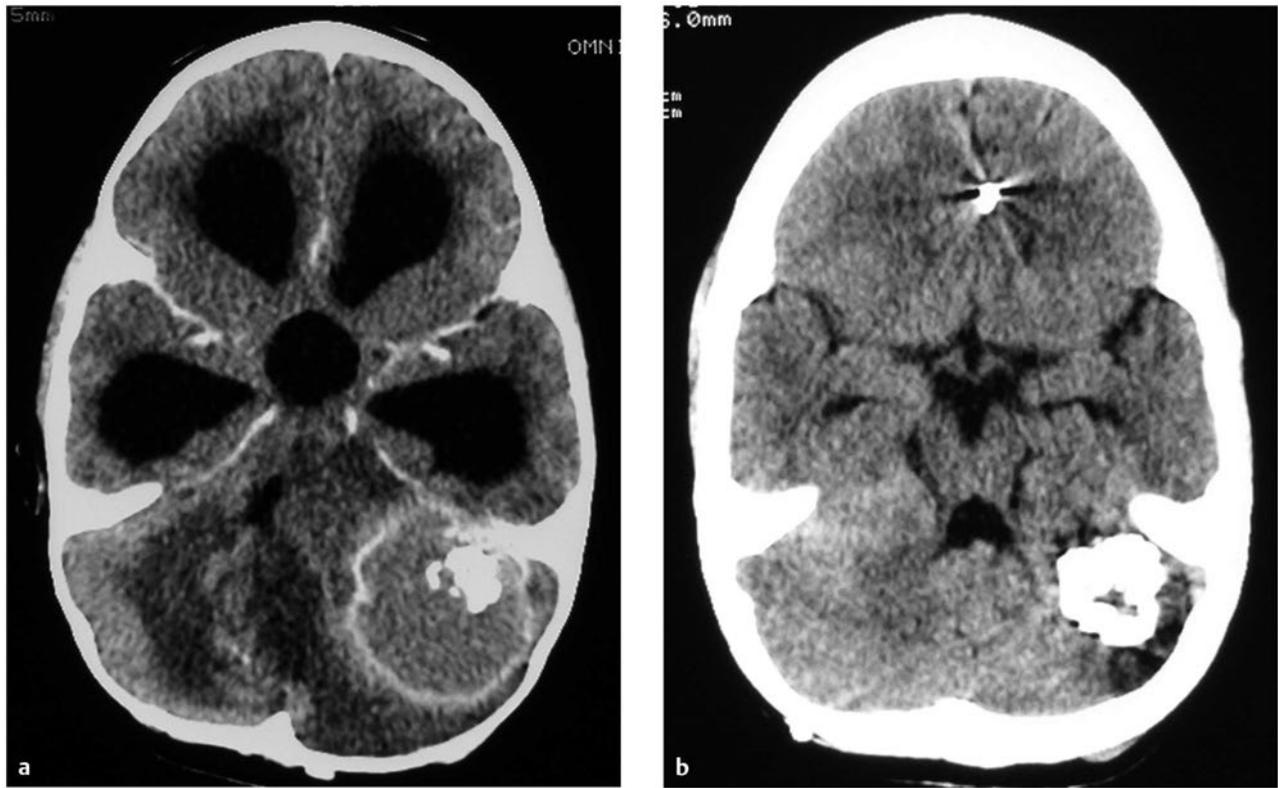

Fig. 80.3 Posterior fossa tuberculoma. (a) This patient presented with hydrocephalus, which was treated with a ventriculoperitoneal shunt, although our current practice is to consider an endoscopic third ventriculostomy. (b) The lesion responded well to antituberculous treatment.

common CNS parasitic infestation in humans and a leading cause of acquired epilepsy.⁶¹

Cysticercosis is widely endemic in those parts of the developing world where pork is consumed and sanitation is poor.⁶² *T. solium* infection is endemic in Central and South America and in non-Islamic regions of Asia and sub-Saharan Africa. In certain developed countries, the prevalence appears to be rising as a consequence of the increasing migrant workforce,^{63–65}

with some authors suggesting that the screening of potentially “at-risk” household employees be considered before employment.⁶⁶

The life cycle of *T. solium* involves pigs as intermediate hosts, after they ingest the eggs, and humans as definitive hosts, when they harbor the egg-producing adult tapeworm. The cycle is completed when a human inadvertently consumes mealy pork contaminated with viable *T. solium* eggs. The oncospheres enter

Table 80.1 Comparison of neurocysticercal and tuberculous lesions

	Neurocysticercal lesion	Tuberculous lesion
Number	Usually single, can be multiple	May be single or multiple
Location	Usually frontal and parietal lobes	Can occur supratentorially or infratentorially
Edema	Minimal, depends on phase of development, midline shift unusual	Extensive surrounding edema, often with midline shift
Size	Dimension < 20 mm	Dimension > 20 mm
Enhancement pattern	Usually ring-enhancing, may have central hyperdensity (scolex); calcification usually indicates inactive lesion	Heterogeneous enhancement
Clinical features	Usually presents with seizures, raised intracranial pressure or progressive neurologic deficit rare	Usually features of raised intracranial pressure and/or progressive neurologic deficit
Disease course	Usually self-limiting, may require antiepileptic drugs for seizure control	Antituberculous medication required for progressive disease
Systemic involvement	None	May have systemic or pulmonary tuberculosis

the mucosa of the small intestine, mature over a 2- or 3-month period, and then spread hematogenously, displaying a predilection for muscle, brain, and skin.⁶⁷ Humans may also be autoinfected, either externally (fecal-oral route) or internally (reverse peristalsis). Between 5 and 40% of adult carriers of *T. solium* will develop cysticercosis.⁶⁸

Once an oncosphere enters the brain parenchyma, it develops through four identifiable phases: (1) vesicular phase (viable cyst with minimal host response); (2) colloidal phase (rupture of a degenerating cyst into surrounding parenchyma, inciting a strong immune response); (3) granular-nodular phase (further degeneration, with formation of a nodular cyst); and (4) calcified phase (death and calcification of the cyst).⁶⁹

Immunocompromised patients appear more susceptible to multiple-organ involvement, with HIV coinfection in neurocysticercosis increasing the risk for basilar meningitis and the formation of giant cysts.^{70,71} The effect of HIV infection on the natural history of neurocysticercosis, however, remains unclear.⁷² Carpio et al⁷³ have proposed a useful classification for neurocysticercosis based on viability and location: active when the parasite is alive, transitional if it is degenerating, and inactive if the parasite is dead. Each of these categories can be subclassified as parenchymal or extraparenchymal (i.e., meningeal, intraventricular, and subarachnoid forms).^{73,74} Traditionally, the term *cysticercus cellulosae* is used to describe thin-walled, 3- to 20-mm cysts (containing scolices) occurring within the parenchyma, and *cysticercus racemosus* to describe larger, “grapelike” vesicles (without scolices), usually located in the basal cisterns, ventricles, or sylvian fissure.^{69,75}

The clinical manifestations of neurocysticercosis vary, depending on the number, size, location, and developmental stage of the cysticercal lesions, as well as the host immune response.⁷⁶ The most common clinical manifestations are seizures, headache, and focal neurologic deficits. The parenchymal form presents with seizures or focal neurologic deficits caused by direct compression. The meningeal form may present with signs of raised ICP that is due to widespread arachnoiditis and adhesions leading to hydrocephalus. Cranial nerve palsies may be caused by vasculitis or fibrous adhesions. The intraventricular or cisternal form presents mostly with raised ICP due to hydrocephalus resulting from the obstruction of CSF flow. This form tends to be rapidly progressive.⁷⁷ Rarer neurologic manifestations include neurocognitive impairment, altered mental state, brainstem dysfunction, strokelike symptoms, and extrapyramidal signs.⁵⁹

Diagnostic criteria based on objective clinical findings, imaging features, and immunologic and epidemiologic data have been proposed.⁷⁸ In a hospital-based setting, however, neuroimaging remains the mainstay, with a definitive diagnosis made on the basis of histopathologic evidence. Lateral X-rays of the thigh and calf, in suspected cases of cysticercosis, often demonstrate cigar-shaped calcifications and may be useful in confirming the diagnosis. CT scans in the active phase of the disease demonstrate hypodense lesions, which may be single or multiple and of varying size, containing a hyperdense mural nodule (► Fig. 80.4). Ring enhancement is suggestive of perilesional inflammation, and calcification, which denotes inactive, degenerated lesions, is present in 50% of cases. MR imaging is more sensitive in demonstrating smaller cysts within the ventricular and subarachnoid spaces as well as the various stages of

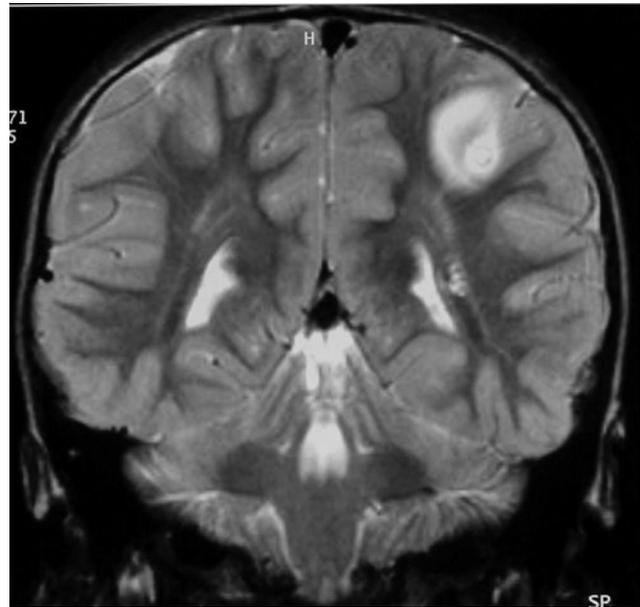

Fig. 80.4 Solitary neurocysticercus on T2 MR image (a) and anatomical pathology specimen (b) of an encysted cysticercus metacestode displaying a protoscolex. The germinal tissue forming the cyst wall is not marginated, consistent with viability and likely complete absence of contrast enhancement. (Courtesy of Dr. Richard Hewlett.)

development of the parasite. The cysts display distinctive features on both T1- and T2-weighted imaging.⁷⁹

Laboratory studies are useful in confirming the diagnosis. CSF mononuclear pleocytosis with raised protein and low glucose levels are typical findings in extraparenchymal disease, particularly with arachnoiditis.⁸⁰ Immunodiagnostic methods capable of detecting antibodies include complement fixation, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and enzyme-linked immunoelectrotransfer blot (EITB). ELISA and EITB are the most frequently used tests for the diagnosis of human cysticercosis, with EITB demonstrating 90% sensitivity for detecting human cysticercosis, but a much lower sensitivity for detecting single intracerebral lesions.⁸¹ In children with a single intracerebral lesion, EITB can yield false-negative results in 75% of cases.⁸² Serologic results, therefore, need to be interpreted together with clinical and radiologic findings.

The treatment modalities for neurocysticercosis include antiparasitic agents, symptomatic medication, and surgery. Guidelines proposed in 2002⁸³ suggest that there is insufficient evidence to support the recommendation of the antihelminthic drugs praziquantel and albendazole in neurocysticercosis and therefore recommend that treatment be individualized in terms of burden of disease and clinical presentation. Antihelminthic drugs are generally considered useful for long-term seizure control and for persisting or enlarging parenchymal lesions.⁸³ Albendazole appears superior to praziquantel because the latter has less efficacy for extraparenchymal lesions, interacts with steroids and antiepileptics, and may increase the risk for stroke.⁸⁴⁻⁸⁶ Antihelminthics should be used with caution in patients in whom raised ICP is suspected because the inflammatory response they evoke can precipitate further neurologic deterioration.

The use of corticosteroids in conjunction with antihelminthics is generally recommended because they reduce the inflammatory reaction caused by the death of the larvae and are beneficial in cases of cysticercotic encephalitis, as well as in cases with involvement of the meninges and subarachnoid space. Antiepileptic drugs remain the principal therapy for seizure control in neurocysticercosis.⁸³ Standard first-line antiepileptic drugs are usually adequate as single agents. The duration of treatment is controversial, however, and gradual cessation of the medication after resolution of the parasitic infection on imaging studies has been recommended.^{61–63} Standard treatment regimens appear effective in immunocompromised hosts, but the impact of antiretroviral therapy and immune reconstitution on the severity of the disease remains uncertain.⁷²

Neurosurgical intervention is indicated for (1) obtaining a tissue diagnosis, (2) relieving mass effect caused by the cyst, (3) treating raised ICP, (4) diverting the CSF to manage hydrocephalus, and (5) decompressing a compressed spinal cord and roots. A tissue diagnosis can be obtained via stereotactic biopsy or open craniotomy and resection of the lesion. Patients with neurocysts causing significant mass effect may require a craniotomy for adequate exposure and removal, and those with raised ICP due to hydrocephalus may require insertion of an external ventricular drain as a temporizing measure. Rates of ventriculoperitoneal shunt failure in neurocysticercosis are reportedly as high as 67%.⁸⁷ Endoscopic approaches have gained increasing popularity for removing ventricular neurocysts, either as stand-alone treatments or in combination with ETV to treat hydrocephalus.^{88,89} In this setting, ETV is most useful when there is a noninflammatory obstruction at the level of the aqueduct.⁹⁰

Patients with parenchymal forms of neurocysticercosis have a better prognosis than those with the extraparenchymal form, particularly when the latter causes hydrocephalus and arachnoiditis.⁹¹ The eradication of cysticercosis remains dependent on prevention, which requires improvement in human sanitation and the public health infrastructure. This disease remains a biological marker of poverty and social disparity.

80.2.2 Echinococcosis (Hydatid Disease)

Hydatid disease is caused by the cestode *Echinococcus*. The disease is prevalent worldwide but is endemic in the sheep- and cattle-raising areas of the world, particularly Latin America, Australia, Mediterranean countries, the Middle East, and India. The most common genus found in humans is *Echinococcus granulosus*, with *Echinococcus multilocularis* and *Echinococcus vogeli* seen rarely. The definitive hosts for *Echinococcus* are canines, such as dogs, wolves, and foxes.⁹² Humans inadvertently serve as intermediate hosts by ingesting food contaminated with dog feces containing viable parasite eggs. The eggs form oncospheres in the human intestine, penetrate the mucosa, and spread hematogenously to the liver (75%), lungs (15%), and brain (2%).^{93,94} They usually grow at a rate of 1 cm per year, but growth of 5 to 10 cm within the first year has been reported,⁹⁵ and the eggs are able to survive for many years. Although cerebral involvement is rare, the majority of cases of cystic hydatid disease, up to 75%, are found in children.^{96–98} Most cysts are single and unilocular and are located in the distribution of the middle cerebral artery, but they may also

occur infratentorially.⁹² Rupture of the cyst is uncommon but may occur spontaneously or as a result of trauma.

There is a wide spectrum of clinical presentations in cerebral hydatid disease, with the presentation depending on the number, size, and location of the cysts as well as on the host immune response. Most patients present with symptoms and signs of raised ICP (i.e., headache, nausea, vomiting, papilledema, and focal neurologic deficit). Seizures may occur but are uncommon.

Hydatid disease can be diagnosed in a patient with an appropriate history (resident in an area where the disease is endemic) based on the imaging and clinical findings, supported by serologic tests or the definitive identification of *E. granulosus* on histopathology. Serologic tests have a low sensitivity in cerebral hydatid disease, and characteristic imaging findings may still be diagnostic despite negative serology.^{92,93,99} Cerebral hydatid cysts appear as large, unilocular, thin-walled cysts, usually without calcification or surrounding edema, containing fluid with a density similar to that of CSF on CT scans and MR imaging (► Fig. 80.5). Calcification on a CT scan usually signifies death of the parasite, but areas of calcification and irregularity along the cyst wall may suggest previous rupture.¹⁰⁰

The treatment of cerebral hydatid disease remains primarily surgical,¹⁰¹ with antihelminthic therapy (benzimidazoles) given as adjunctive treatment for systemic disease, recurrence, or intraoperative rupture of a cyst.¹⁰² The goal is intact removal of the cyst without spillage of the contents. Dowling's technique,¹⁰³ in which hydrostatic dissection is used to define the plane between the delicate cyst wall and brain parenchyma, remains a popular method of in toto cyst extirpation. The surgical principles for removal of a cerebral hydatid cyst involve a large craniotomy, careful opening of the dura (particularly in the case of a superficially located cyst), and microsurgical dissection of the cortex with adequate exposure of the cyst wall. Fine-bore catheters are gently inserted between the cyst wall and cortex, and normal saline (0.9%) is used for hydrodissection of the cyst wall from the parenchyma; simultaneous adjustment of the position of the patient's head and mild Valsalva may gently encourage the cyst to emerge. The placement of swabs soaked in hypertonic (5%) saline around the area of the cyst is helpful in the event of spillage, but care must be taken to avoid excessive systemic absorption. Intraoperative ultrasound may be useful in defining the borders of the cyst, especially if it is deeply located. Watertight dural and skin closure is essential. Cyst rupture during surgery is almost inevitably associated with recurrence and is an indication for the commencement of antihelminthic therapy.¹⁰² Cyst aspiration has been described but should be considered only when intact removal of the cyst is not possible. Usually, the brain re-expands to a remarkable extent within months, but occasionally postoperative complications may be seen, such as subdural collections or porencephalic cysts, seizures, and transient neurologic deficits. Mass effect from the subdural collection or porencephalic cyst may require shunt placement.^{101,104}

Spinal hydatid disease in children is rare and may be either intradural or extradural, involving the vertebrae. In the latter case, intact removal is almost impossible, whereas laminectomy and intact cyst removal usually provide the best results for intradural cysts. The reported recurrence rate of spinal hydatid

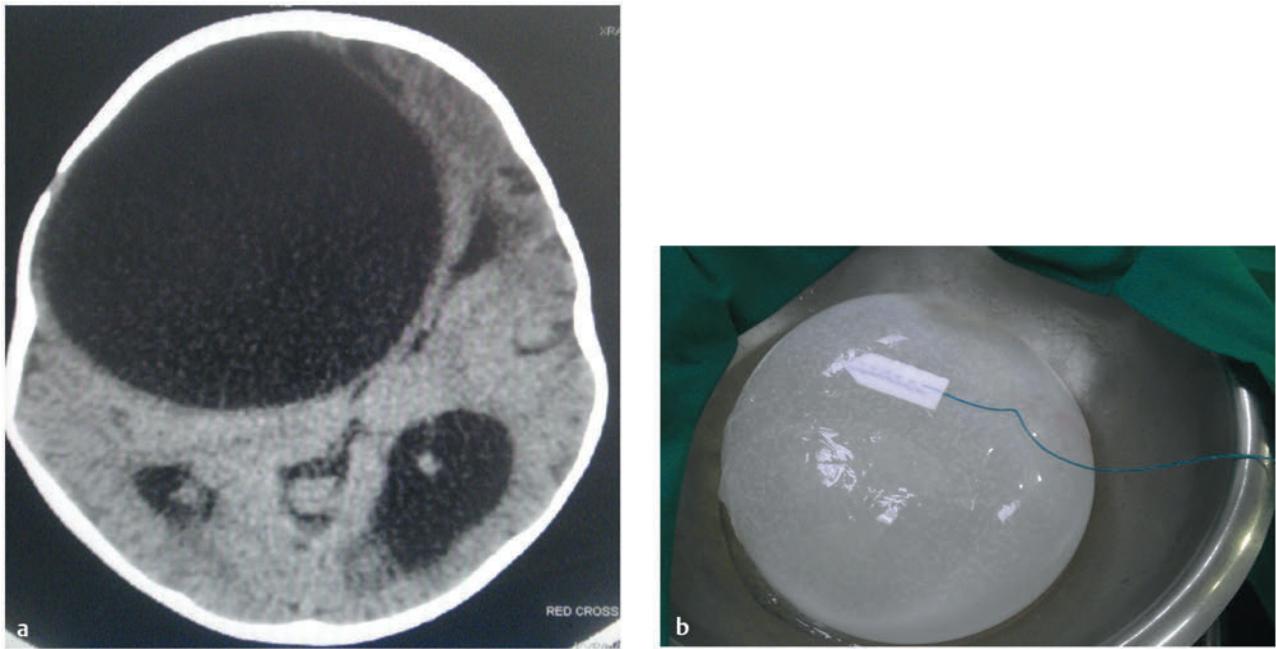

Fig. 80.5 (a) Very large frontal hydatid cyst seen on axial computed tomographic scan and (b) operative specimen following removal.

disease is about 40%, so careful clinical and imaging follow-up is necessary.^{105,106}

Hydatid cysts must be considered in the differential diagnosis of cystic lesions involving the CNS, particularly in regions where they are endemic. Early surgical treatment with intact cyst removal yields the best outcome.

80.2.3 Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan parasite, first recognized in the human retina in 1928.¹⁰⁷ Toxoplasmosis has a worldwide distribution. Felines are definitive hosts and excrete infectious feces, with humans and other mammals serving as intermediate hosts.

Toxoplasmosis in humans may be either acquired or congenital. The acquired form is associated with direct or insidious contact with cat feces, the consumption of contaminated fruit and vegetables, or the ingestion of oocytes in undercooked, contaminated meat. Congenital toxoplasmosis is transmitted during acute infection in pregnancy, with 1 per 1,000 pregnant women acquiring *T. gondii* infection during pregnancy.¹⁰⁸ The rate of fetal transmission is directly related to the gestational age at transmission, with the rate of transmission increasing with each trimester.¹⁰⁹ The increasing number of patients with immunocompromise, due either to HIV infection or to immunosuppression, has led to the emergence of toxoplasmosis as a potentially life-threatening opportunistic infection.¹¹⁰

The parasite invades the human intestine and multiplies; in the acute form of the infection, tachyzoites then disseminate hematogenously throughout the body. In CNS infection, diffuse involvement of the gray matter results in meningoencephalitis, with foci of perivascular inflammation.¹¹¹ Basal ganglionic and periventricular calcification has been reported in the fetus.¹¹² In congenital toxoplasmosis, hydrocephalus may result

from obstruction at the foramen of Monro or aqueduct of Sylvius. In immunocompromised hosts, widespread necrotizing lesions may occur within the CNS and other organs.¹¹³

The disease in children is classified as congenital, postnatally acquired, or ocular.

Congenital toxoplasmosis is often subclinical but may have a wide spectrum of clinical presentations, including the classic features of fever, hydrocephalus, chorioretinitis, cerebral calcification, seizures, microcephaly, and CSF abnormalities (markedly raised protein and mononuclear pleocytosis); systemic presentations, such as hepatosplenomegaly and jaundice, are also possible.^{114,115} The severity of the clinical disease in congenitally infected infants is inversely related to the gestational age at the time of maternal infection, with severe disease or death in 40 to 79% of fetuses infected in the first trimester, in 15 to 18% of fetuses infected in the second trimester, and in 0 to 3% of fetuses infected in the third trimester.¹⁰⁹ Congenital toxoplasmosis must be differentiated from other perinatal encephalopathies, which may coexist or present similarly. These include cytomegalovirus, herpes simplex virus, and rubella virus infections and certain metabolic and storage diseases.¹¹⁶

Acquired toxoplasmosis remains asymptomatic in most cases, with only 10 to 15% of patients exhibiting clinical symptoms and signs.¹¹⁶ In acquired toxoplasmosis involving the CNS, the predominant neurologic symptoms are headache, disorientation, and drowsiness, and toxoplasmosis should be considered in the differential diagnosis whenever evidence of acute CNS disease is noted.

Serologic tests remain the most common method of establishing the diagnosis. Fetal testing is indicated when *Toxoplasma* infection is identified either immediately before or during pregnancy. The detection of immunoglobulin M (IgM)-specific antibody in fetal blood or the isolation of *T. gondii* in amniotic fluid via cordocentesis or amniocentesis, respectively, has been used

to make the diagnosis of toxoplasmosis prenatally.^{117,118} Repeated fetal ultrasound demonstrates rapidly progressive, symmetric ventricular dilatation as the most common finding.¹¹⁹ When fetal toxoplasmosis is confirmed, antibiotic treatment with sulfadiazine and pyrimethamine together with folinic acid is recommended until delivery.¹¹⁶ A significant reduction in the severity of the clinical sequelae associated with congenital toxoplasmosis has been demonstrated with the use of spiramycin, pyrimethamine, and sulfonamides.¹²⁰ The diagnosis of congenital toxoplasmosis can be made through a combination of clinical examination, radiologic imaging, and CSF and serologic analysis, as well the isolation of *T. gondii* organisms from tissue or fluid specimens in acute infection (may take 4 to 6 weeks).

The postnatal treatment of congenital toxoplasmosis with pyrimethamine, sulfadiazine, folinic acid, and prednisone is recommended. Prednisone is indicated if the CSF protein is elevated or if sight-threatening chorioretinitis is present and is continued until either of these resolves.¹¹⁶ Untreated congenital toxoplasmosis carries a poor prognosis, but current treatment regimens, prolonged for 1 year, appear to substantially decrease the frequency and severity of neurologic sequelae.^{121,122} The coexistence of toxoplasmosis and HIV infection is rarer in children than in adults,¹²³ especially since the advent of HAART (highly active antiretroviral therapy). The treatment regimen with HIV infection, however, remains unchanged.

Hydrocephalus remains the condition most commonly associated with congenital toxoplasmosis and requires neurosurgical intervention. The pathogenesis of hydrocephalus in this setting is unclear, with studies suggesting both obstruction at the foramina and aqueduct of Sylvius and impaired absorption at the arachnoid villi as possible mechanisms.^{124,125} The nature of the hydrocephalus (i.e., obstructive or nonobstructive) has important implications regarding the options for treatment (ventriculoperitoneal shunt or ETV).

Toxoplasmosis of the CNS occurs in up to 40% of all HIV-infected patients and is the most common opportunistic infection to cause focal brain lesions.^{126,127} Acquired toxoplasmosis in children and adults is often asymptomatic. Three different neurologic patterns are evident in toxoplasmosis of the CNS: diffuse encephalitis with or without seizures, meningoencephalitis, and single or multiple mass lesions.¹²⁸

The diagnosis of toxoplasmosis of the CNS is based on a history of exposure and the presence of risk factors, the clinical examination, serologic and CSF testing (when lumbar puncture is safe), and radiologic features on CT and/or MR imaging. On radiologic imaging, cerebral toxoplasmic lesions often appear as multiple lesions (often more than five lesions), show ring enhancement with contrast, are typically located in the basal ganglia or at the gray–white matter interface, have minimal mass effect with mild edema, and often show evidence of cerebral atrophy.

As above, pyrimethamine, sulfadiazine, and folinic acid are recommended. Surgical intervention is reserved for biopsy in cases of diagnostic uncertainty, for the relief of mass effect, or for the prevention of impending herniation. The prognosis of patients with toxoplasmosis involving the CNS, particularly those who are immunocompromised, is poor. In a study of HIV-infected patients with toxoplasmosis of the CNS, fewer than half survived to 14 months after the initial diagnosis.^{129,130} Children with immunosuppression and acquired toxoplasmosis also have

high rates of mortality and neurologic sequelae.¹³¹ An early diagnosis and aggressive treatment are essential to obtaining the best possible outcome.

Prevention is vital in reducing both congenital and acquired toxoplasmosis. Pregnant women and immunosuppressed patients, and their families, should avoid contact with cat litter, cook meat to higher than 150°F, wash fruit and vegetables thoroughly, and clean cooking surfaces carefully. If seropositivity with a risk for congenital transmission is confirmed, treatment with antibiotic therapy should be initiated immediately.

80.2.4 Amebic Encephalitis

The first human cases of amebic encephalitis were reported in 1965 by Fowler and Carter.¹³² Free living amebae are found worldwide and thrive in warm, aquatic environments. Those causing CNS infection include *Balamuthia mandrillaris*, *Entamoeba histolytica*, and *Naegleria fowleri*. Amebic CNS involvement is rare but is almost always fatal. Primary amebic meningoencephalitis is typically caused by *N. fowleri*, with the other amebae usually causing a subacute or chronic form of infection known as granulomatous amebic encephalitis.

Patients who have primary amebic meningoencephalitis typically present with fever, severe headache, and symptoms of raised ICP within 2 weeks of exposure to contaminated water. Rapid progression to coma and death is the usual clinical scenario. Neuroimaging may be useful, but the definitive diagnosis is made via a wet mount of the CSF to detect motile trophozoites. The course in granulomatous amebic encephalitis is usually more protracted, lasting weeks to months, and the disease most commonly affects immunocompromised patients, often as an opportunistic infection in those with HIV infection.¹³³ The symptoms are nonspecific initially and evolve to altered mental status and focal neurologic deficit due to the space-occupying lesion. Patients generally progress to death within several weeks. Rapid diagnosis remains dependent on a detailed history looking for recent exposure to stagnant water bodies, a focused clinical examination, imaging features, and identification of the organism on wet smear.¹³⁴ Aggressive treatment strategies include antimicrobials, such as amphotericin B and metronidazole, with steroids and osmolar therapy as adjuncts in patients with raised ICP. Surgery may be necessary in cases with raised ICP and space-occupying lesions.

80.2.5 Schistosomiasis

Schistosomiasis is an infection caused by flukes of the genus *Schistosoma*. Three species—namely, *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum*—lead to CNS involvement. Affecting up to 300 million people worldwide each year, schistosomiasis is the second most common parasitic infestation, after malaria, and is most frequently transmitted through contact with contaminated water bodies. Cerebral schistosomiasis typically manifests pathologically as space-occupying lesions, either single or multiple cerebral hemispheric lesions or nonspecific granulomas with surrounding edema.¹³⁵ The clinical presentation includes headache, altered mental state, seizures, and focal neurologic deficit, which usually commence weeks after the initial contact. CT or MR imaging usually demonstrates nodular, ring-enhancing intraparenchymal

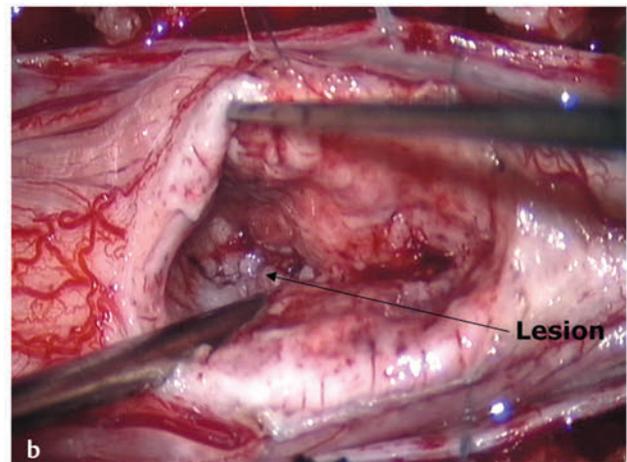

Fig. 80.6 A 10-year-old boy from East Africa was referred with progressive leg weakness and sphincter involvement. (a) Gadolinium-enhanced T1 magnetic resonance imaging showed an intramedullary mass thought to be a neoplasm, but (b) schistosomiasis was found following myelotomy.

lesions. Spinal cord infection, usually in the form of transverse myelitis, most frequently involves the conus medullaris or cauda equina.¹³⁶ Identification of the larva on a histopathologic specimen remains the gold standard for diagnosis (► Fig. 80.6). The antischistosomal drug praziquantel remains the mainstay of medical treatment. Surgical resection or biopsy may be required, depending on the size and location of the lesion.¹³⁷

80.2.6 Cerebral Malaria

Cerebral malaria is usually caused by infection with *Plasmodium falciparum* but rarely can be caused by *Plasmodium vivax*. Cerebral malaria, even with treatment and supportive care, has a reported mortality rate of 20 to 50%, the vast majority of fatalities occurring in African children.^{138,139} Fever is the clinical hallmark of cerebral malaria; other diagnostic features include coma, seizures, identification of *P. falciparum* or *P. vivax* on blood smear, and the exclusion of other causes of encephalopathy.¹⁴⁰ Management includes adequate resuscitation, supportive care, and the commencement of antimalarial treatment, the details of which fall beyond the scope of this chapter.

80.3 Fungal Infections

Fungi are ubiquitous in the environment but seldom pathogenic.¹⁴¹ Fungal invasion of the CNS generally produces one or more of the following pathologic scenarios: subacute or chronic meningitis, encephalitis, parenchymal brain abscesses or granulomas, and vasculitis or vascular thrombosis leading to ischemic injury. The diagnosis is usually made in a vulnerable patient with a history of exposure and is confirmed by serologic tests, CSF analysis, or histopathologic examination. Treatment with long-term courses of antifungal medication is usually required, and surgery for CSF diversion may be indicated in patients in whom hydrocephalus develops. Some of the more common CNS fungal infections are briefly discussed here, and ► Table 80.2 provides a more complete list.

Cryptococcosis is caused by *Cryptococcus neoformans*, an encapsulated yeast found worldwide. CNS infection with cryptococci is usually an opportunistic infection in immunocompromised patients. The clinical pattern is typical of meningitis, often with features of raised ICP. Laboratory diagnosis is usually made with India ink stain, but a serologic test (cryptococcal latex antigen test) is also available. Therapy usually includes amphotericin B with flucytosine (for 2 weeks), followed by oral

Table 80.2 Features of common fungal infections of the central nervous system

Fungal infection	Features
Cryptococcosis	Etiologic agent: <i>Cryptococcus neoformans</i> Found in pigeon droppings and soil Affects mainly immunocompromised patients Typically “pseudocysts” in the basal ganglia Raised intracranial pressure Meningitis ¹⁴²
Aspergillosis	Etiologic agents: <i>Aspergillus fumigatus</i> , <i>A. flavus</i> , <i>A. nidulans</i> , <i>A. niger</i> Angioinvasive, leading to arterial thrombosis Solitary or multiple abscesses, meningitis, granuloma, or mycotic aneurysms ^{141,143}
Candidiasis	Etiologic agents: <i>Candida albicans</i> , <i>C. glabrata</i> Less common: <i>C. tropicalis</i> , <i>C. parapsilosis</i> , <i>C. krusei</i> Normal flora in mouth and gastrointestinal tract Low-birth-weight infants, critically ill patients, and surgical patients most at risk ¹⁴⁴ Meningitis and hydrocephalus
Histoplasmosis	Etiologic agent: <i>Histoplasma capsulatum</i> Found in soil contaminated with bird droppings Meningitis, encephalitis, multiple mass lesions of the brain or spinal cord ¹⁴¹
Blastomycosis	Etiologic agent: <i>Blastomyces dermatitidis</i> Found in moist soil Central nervous system involvement in 5 to 10% of patients with disseminated disease Meningitis, hydrocephalus, cerebral abscesses, or blastomycomas (granulomatous masses) ¹⁴¹
Coccidioidomycosis	Etiologic agent: <i>Coccidioides immitis</i> Found in soil Meningitis with secondary obstructive hydrocephalus, brain abscess ¹⁴⁵
Nocardiosis	Etiologic agent: <i>Nocardia asteroides</i> Usually affects immunocompromised patients Brain abscess

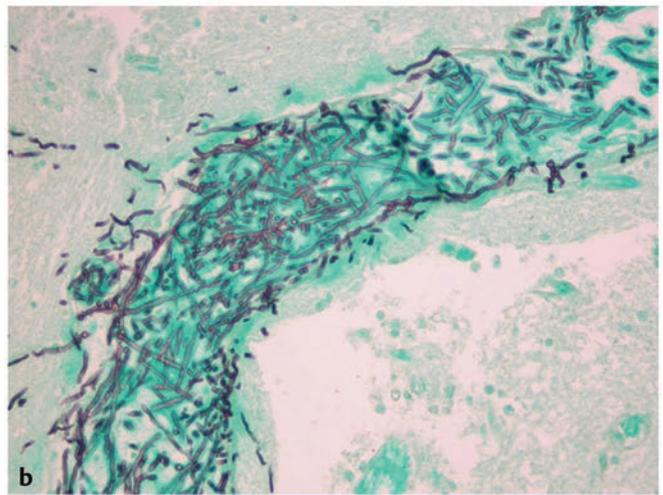

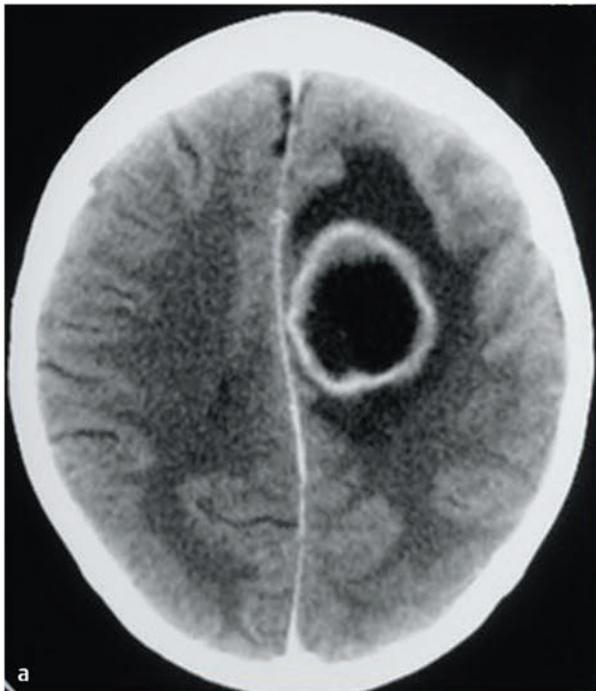

Fig. 80.7 One month after starting chemotherapy for leukemia, an 11-year-old boy developed a right hemiparesis. (a) Contrast-enhanced computed tomographic scan showed a ring-enhancing mass, which was excised. (b) Histology confirmed aspergillosis with evidence of vascular invasion on silver stain.

fluconazole for 8 weeks. Raised ICP can be managed with serial lumbar punctures, although a lumboperitoneal shunt may be required in patients in whom hydrocephalus develops.¹⁴²

CNS aspergillosis is usually caused by the organism *Aspergillus fumigatus*. Infection most commonly presents as an abscess and less commonly as meningitis. Excision of these lesions is recommended because they have a propensity for vascular invasion (► Fig. 80.7), which is followed by the formation of mycotic aneurysms. Combination therapy with the newer antifungal drugs and surgery has improved outcome.¹⁴³

Candida species are the most common pathogens in patients with end-stage AIDS. They often colonize central lines, external ventricular drains, and shunts. They can therefore either complicate the treatment of underlying hydrocephalus or be the causative organism.¹⁴⁴

Coccidioidomycosis, caused by the dimorphic fungus *Coccidioides immitis*, is endemic to semiarid regions. CNS infection is seen mostly in immunocompromised patients, usually with basal meningitis that often leads to hydrocephalus. Early shunt placement is often required, together with antifungal therapy.¹⁴⁵

Pearls

- Hyponatremia and imaging findings of basal meningeal enhancement, hypodense lesions in the basal ganglia, and hydrocephalus are common in TBM.
- Tuberculous vasculitis resulting in cerebral ischemia remains the most important cause of neurologic deterioration in TBM.
- Neurocysticercosis is a leading cause of acquired epilepsy.
- Hydatid disease must be borne in mind in the differential diagnosis for cystic lesions of the CNS, especially in areas where hydatid disease is endemic.
- Toxoplasmosis is the most common opportunistic infection causing focal brain lesions in patients infected with HIV.

80.4 Acknowledgments

The authors would like to thank Professor Richard Hewlett and Dr. Komala Pillay (Department of Clinical Laboratory Sciences, University of Cape Town), Professor Tony Figaji (Red Cross War Memorial Children's Hospital, Cape Town, South Africa), and Professor Vedantam Rajshekhar (Christian Medical College, Vellore, India) for their assistance.

81 Infections of the Spinal Axis

Jeffrey P. Blount, Robert P. Naftel, Benjamin J. Ditty, and Michael J. Conklin

Infections of the spinal axis are an important although uncommon group of diseases that often present with insidious and variably progressive symptoms. The classic clinical hallmarks of infectious disease, such as fever, are variably present. Antimicrobial medical therapy constitutes the cornerstone of rational therapy if diagnosis occurs early. However, delay in diagnosis is common. Surgical intervention makes it possible to obtain tissue or fluid for microbiological diagnosis, drain localized abscesses, relieve compression of neurologic structures, or reconstruct segments of the bony spine destroyed by infection. With advances in imaging, antimicrobial chemotherapy, and the development of safe surgical methods of radical resection and reconstruction of collapsed vertebral segments, there exists the potential to treat and ameliorate the devastating morbidity and mortality that have long been associated with this group of diseases. Spinal infections in children are less completely characterized than those in adults because more of the medical literature consists of case reports and small case series.

81.1 Pyogenic Infections of the Spinal Axis

The pyogenic infections include infections of the vertebral bodies (spondylitis), facet joints (spondylitic arthropathies), intervertebral disks (spondylodiskitis), and epidural space (epidural abscess).^{1,2} Infections within the dura (subdural empyema, intraparenchymal spinal cord abscess) have been described but are vanishingly rare in the absence of a congenital dysraphic defect, such as a dermal sinus tract, or severe bacterial meningitis. In pyogenic infections, the offending bacteria elicit an inflammatory response that follows a usual acute phase inflammatory reaction (humoral immunity). As such, the predominant leukocytes in the region of inflammation are polymorphonuclear neutrophils. Large populations of lysed polymorphonuclear neutrophils and local necrotic tissue give rise to the purulence for which pyogenic infections are named. The offending bacteria are most commonly staphylococci and streptococci, but gram-negative organisms and *Propionibacterium acnes* have been identified and implicated.³ There has been a pronounced recent increase in the incidence of postoperative pyogenic infections with methicillin-resistant *Staphylococcus aureus* (MRSA).⁴ In at least one-third of cases, an offending organism is never identified. Unlike the microorganisms that cause pyogenic infections, acid-fast microorganisms (e.g., *Mycobacterium tuberculosis*) and fungi characteristically give rise to a chronic granulomatous type of inflammatory response.^{2,5}

81.1.1 Diskitis

Diskitis in children is a well-recognized although rare clinical entity that may characteristically present three to four times per year in a busy primary pediatric center.⁶ The disease occurs spontaneously in young children and involves inflammation of the intervertebral disk or cartilaginous vertebral end plate.^{7,8} Diskitis affects children of all ages, but its prevalence is highest

in children younger than 5 years of age.^{6,8} The incidence of diskitis rises again in adolescents for unknown reasons. Diskitis may occur at any spinal level, but case series indicate that lumbosacral disease occurs more commonly than thoracic disease, which occurs more commonly than cervical disease.⁸

The etiology of spontaneous diskitis is controversial because negative needle biopsy culture rates of 30 to 50% have been repeatedly demonstrated. Some cases of pediatric spontaneous diskitis have also been observed to resolve without treatment. These observations have prompted some centers to consider it a benign, self-limited process and to characterize childhood spontaneous diskitis as either sterile or infectious. However, the theory of an infectious etiology remains most widely held, in which diskitis results from the hematogenous spread of infection from a remote site, such as the urinary or respiratory tract.^{6,8} Alternative routes of infection in adults include iatrogenic inoculation during surgery or other invasive procedures and direct extension from adjacent infected tissues.⁹

Children are at greater risk than adults for the hematogenous spread of infection to the disk space. In children younger than 8 years, a robust network of vessels spans from the cartilaginous vertebral end plate to the annulus fibrosus.⁶ The nutrient artery of the central canal gives rise to vascular channels that perforate the vertebral end plates and terminate in the disk space. This network of terminal vessels provides a potential route of direct inoculation of the disk space.^{10,11} The vascular network gradually involutes, with development such that the vascularity is limited to the annulus fibrosus in older children. By adulthood, there is no vascular supply to the disk.^{7,10,11} The cartilaginous end plates of the vertebral bodies serve as an effective barrier to the transmission of infection from the disk space to the vertebral bodies.¹¹ As such, an infectious process beginning in the disk only rarely spreads to involve adjacent vertebrae. Despite resistance to infection from the disk space, the vertebral bodies remain subject to damage by bacterial enzymes and by increased stress caused by deformed and dysfunctional intervertebral disks. Persistent diskitis may result in destruction of the vertebral end plate and exposure of the vertebral body to infection.^{8,9,11}

Clinical Findings

Diskitis often presents with nonspecific symptoms.^{6,8,12} Young children or toddlers often present with a limp or a refusal to stand or walk.^{7,13} The lumbar region is exclusively affected in such children. The assessment can be difficult because young children in pain are often agitated, fearful, and marginally cooperative, and they rarely if ever clearly relate the character or localization of their pain. A toddler with diskitis may crawl normally but refuse to stand and will otherwise appear well. An older child or adolescent may demonstrate a limp or gait impairment.^{8,12,14} Back pain is the most frequent symptom. Children may describe pain in the hips, legs, or genitals. Dysphagia, neck stiffness, and torticollis may accompany diskitis of the cervical spine. Patients are often afebrile or have a low-grade fever and only rarely appear systemically ill. Vague constitutional

symptoms, such as fatigue, weight loss, and appetite changes, may be present but are nonspecific. Therefore, a high index of clinical suspicion for diskitis in any child presenting with low back pain and nonspecific constitutional symptoms expedites the diagnosis and prevents the morbidity that may accompany diagnostic delays.

Children with diskitis do not have neurologic deficits.⁶ Weakness, numbness, or incontinence suggests a compressive lesion, epidural empyema, or intradural infection.^{7,8} Tenderness to palpation around the infected level and spasm of adjacent muscles are common physical examination findings in diskitis.^{14,15} A useful diagnostic examination involves requesting the patient to pick up an object from the floor. Patients with lumbosacral diskitis typically will be unwilling to flex the spine and instead will squat (bend with the knees and ankles and keep the spine in a straight or extended position) to lower the body.¹³

Diagnostic Tests

Laboratory

The initial laboratory evaluation should include a complete blood cell count with differential (CBC), measurement of the C-reactive protein (CRP) level and erythrocyte sedimentation rate (ESR), and blood cultures. If possible, blood cultures should be obtained before the initiation of antibiotic therapy.^{2,12,15,16}

The leukocyte count will often be either normal or slightly elevated. The ESR and CRP are usually slightly higher than normal. Blood cultures can identify the causative organism in as many as 50% of patients with diskitis. This aids in the selection of appropriate antibiotic therapy. If antibiotic therapy has already been initiated and the blood cultures are unrevealing, temporarily withholding antibiotics may be considered in patients who are not declining clinically. In patients with fevers, attempts should be made to collect cultures while the fever is present.^{6-8,12,14}

Radiology

Radiographs of the young child with diskitis (typically demonstrate narrowing of the disk space and may show mild end plate changes if they are obtained several weeks into the illness) (► Fig. 81.1).^{8,14,17} Plain spine radiographs can be highly useful in confirming diskitis and may show changes in up to 76% of patients with diskitis, but they are less often abnormal in cases of vertebral osteomyelitis (46%).¹⁶ Computed tomography (CT) provides a detailed demonstration of the bony changes that occur in response to disk space infection, which may be difficult to appreciate on plain radiographs.¹⁷ CT studies can be obtained relatively quickly, unlike magnetic resonance (MR) imaging, which younger children may be unable to tolerate without sedation.¹⁷

MR imaging provides the best definition of the disk and the paravertebral soft tissues and is particularly useful in separating diskitis from osteomyelitis of the vertebral body. Hypointensity within the vertebral body is characteristic on T1-weighted imaging, representing subchondral fibrosis and bone sclerosis. Hyperintensity may be seen in the disk space and paravertebral tissues on T2-weighted sequences, reflecting tissue edema. The administration of gadolinium can help to define the borders of the infectious process. During monitoring after the completion

Fig. 81.1 Diskitis. Two-year-old female who presented with a 2-week history of back pain, limping and fever. Post-contrast sagittal T1 image shows edema of the L4–5 disc and the adjacent vertebral

of therapy, the T1-weighted and T2-weighted changes may persist despite clearance of the infection.^{14,15,17}

Treatment

The treatment of diskitis is aimed at resolving the infection, eliminating pain, and preventing the development of a more serious infection, such as pyogenic vertebral osteomyelitis (PVO) or epidural abscess. This can be achieved with nonoperative therapy in almost all pediatric cases. Some centers consider diskitis a benign, self-limited process and provide only analgesia and immobilization while the patient is closely observed for progress. Most centers appear, however, to embrace an infectious etiology and an antimicrobial route of management. If an accurate microbiological diagnosis can be obtained via blood cultures, treatment should be initiated with targeted antibiotics. However, it is common that noninvasive testing fails to identify a causative organism. At that point, the clinical options include initiation of a trial of empiric antimicrobial therapy, image-guided (either CT or fluoroscopy) biopsy, or open surgical biopsy.⁹ Virtually all series recommend empiric treatment and the reservation of invasive procedures for cases that fail to respond to 7 to 10 days of intravenous antimicrobial treatment.

The most common offending organism in diskitis depends on the clinical setting. In children with diskitis, *Streptococcus* and *Staphylococcus* species are frequent. In adults, who typically acquire diskitis as a complication of disk surgery (1 to 2%

incidence after elective spinal disk surgery), *Staphylococcus* species predominate. Empiric treatment with a combination of third-generation cephalosporin and oxacillin/clindamycin has been advocated.^{14,16,18,19} Recommendations for the duration of treatment for diskitis vary widely, but there is general agreement that therapy should be initiated with intravenous antibiotics for approximately 7 to 10 days, followed by treatment with oral therapy for 2 to 3 weeks until the symptoms resolve and the CRP level normalizes.^{14,20} Immobilization may contribute to pain control and may be discontinued after the resolution of symptoms⁹ because instability is not a risk of isolated diskitis.

81.1.2 Pyogenic Vertebral Osteomyelitis/Pyogenic Spondylodiskitis

Although insufficiently treated diskitis may evolve to pyogenic vertebral osteomyelitis (PVO), distinct clinical patterns emerge in the spontaneous, de novo presentation of each disorder.^{2,24,25} Vertebral osteomyelitis may demonstrate an acute, subacute, or chronic course that varies with both the age of the patient and the identity of the infecting organism. The child with vertebral osteomyelitis is usually older (past the age of 8 years) and more ill-appearing, and the incidence of fever may be higher.² The incidence of vertebral osteomyelitis peaks in adolescence and again in the later adult years.^{16,24} About 2 to 7% of all cases of osteomyelitis involve the spine, and pyogenic infection is the most prevalent spondylitis.^{23,24} Estimates of incidence range from 0.5 to 2.4 per 100,000 overall, but the numbers separate significantly according to age.^{4,21} In persons younger than 20 years, the incidence is 0.3 per 100,000, but it rises sharply in late adulthood to 6.5 per 100,000.¹⁶ Overall, societal incidence rates are increasing, but this is largely due to an increase in the number of elderly patients who are living longer with a greater burden of partially compensated chronic disease.

Like diskitis, spinal osteomyelitis occurs following the hematogenous spread of microbial pathogens from a remote infectious source.^{1,4,24,26} Infections of the skin, urinary tract, and sinuses are the most frequently implicated, and the majority of spinal infections are preceded by infections elsewhere. Any level of the spine may be affected, but the lumbar region is most frequently involved.¹ The Batson venous plexus is implicated in hematogenous spread to the lumbar region from the bladder and pelvis.^{11,27} Iatrogenic direct inoculation during invasive procedures and spread from an adjacent infection (e.g., psoas abscess) are other mechanisms by which PVO may occur.^{1,22,24,28}

Clinical Findings

PVO is seen more often in older children and young adolescents.^{4,21,23} The initial presentation is usually nonspecific, and symptoms of pain surrounding the involved spinal level predominate.²⁵ Unlike patients with diskitis, those with vertebral osteomyelitis are more likely to present with fever and to appear systemically ill. If neurologic deficits are present, they are secondary to compression of the neural elements^{16,23,27,28} and warrant prompt, aggressive evaluation, imaging, and possible intervention.

Diagnostic Tests

Laboratory

The goals of the laboratory work-up should be the same as in diskitis: to identify and isolate the causative organism to guide therapy. Initial studies should include CBC with differential, ESR, CRP, and blood and urine cultures.^{21,23–25} The CBC often contains an elevated leukocyte count. The ESR and CRP are usually increased (sensitivity, 98 to 100%), and again, serial CRP measurements are useful for monitoring the response to therapy.^{16,22} Blood cultures (sensitivity, 58%; range, 30 to 78%) and biopsy may be indicated in suspected cases of vertebral osteomyelitis.^{15,16,21,24} If the blood cultures are negative, then an image-guided or open biopsy (sensitivity, 77%; range, 47 to 100%) may be indicated if there is no response to empiric treatment. Invasive procedures for diagnosis should not be undertaken until a thorough work-up has failed to identify a microbiological diagnosis and there has been no response to empiric therapy. If an invasive procedure is required, image-guided biopsy typically offers the least morbid option for directly obtaining a tissue sample.

Purified protein derivative (PPD) testing may be helpful but is imperfect in diagnosing tuberculosis (TB) as the cause of vertebral osteomyelitis. TB is a rare cause of osteomyelitis in developed regions. Many children in the developing world will have been immunized with bacille Calmette-Guérin (BCG), which is a vaccine against TB made from an attenuated strain of live bovine TB bacilli. If the presentation is subacute or the history includes exposure to TB or *Brucella* (via the consumption of unsterilized milk), then cultures for *Mycobacterium* and *Brucella* may be helpful.^{2,29} Specific serologic assays, including *Bartonella* species (“cat scratch”), are available and should be considered when exposure to cats is an element of the clinical history or if the results of other investigations have been negative despite clinical indications of PVO.³⁰

Radiology

Plain film radiographs may reveal focal areas of bony erosion early in the course of the illness (► Fig. 81.2). As the disease progresses, destruction of the vertebral body and, potentially, collapse become much more apparent.^{16,17,31} CT studies can further define the extent of bony erosion and destruction.^{15,17,31} MR imaging is useful to separate infections of the vertebral body from those that are limited to the intervertebral disk. MR imaging is more sensitive and specific than other modalities, with demonstrated sensitivity of 96% and specificity of 93% in the diagnosis of vertebral osteomyelitis.^{24,28,30} Vertebral hypointensity on T1-weighted and hyperintensity on T2-weighted sequences represent edema or purulent fluid in the bone marrow or intervertebral disk space. MR imaging, enhanced with the administration of gadolinium, is useful for identifying associated epidural or paravertebral abscesses.^{16,17}

Treatment

Long-term antimicrobial therapy with immobilization is the optimal treatment for osteomyelitis.^{1,16} Empiric treatment, initially with broad-spectrum coverage, is often justified if an organism cannot be identified noninvasively. If cultures

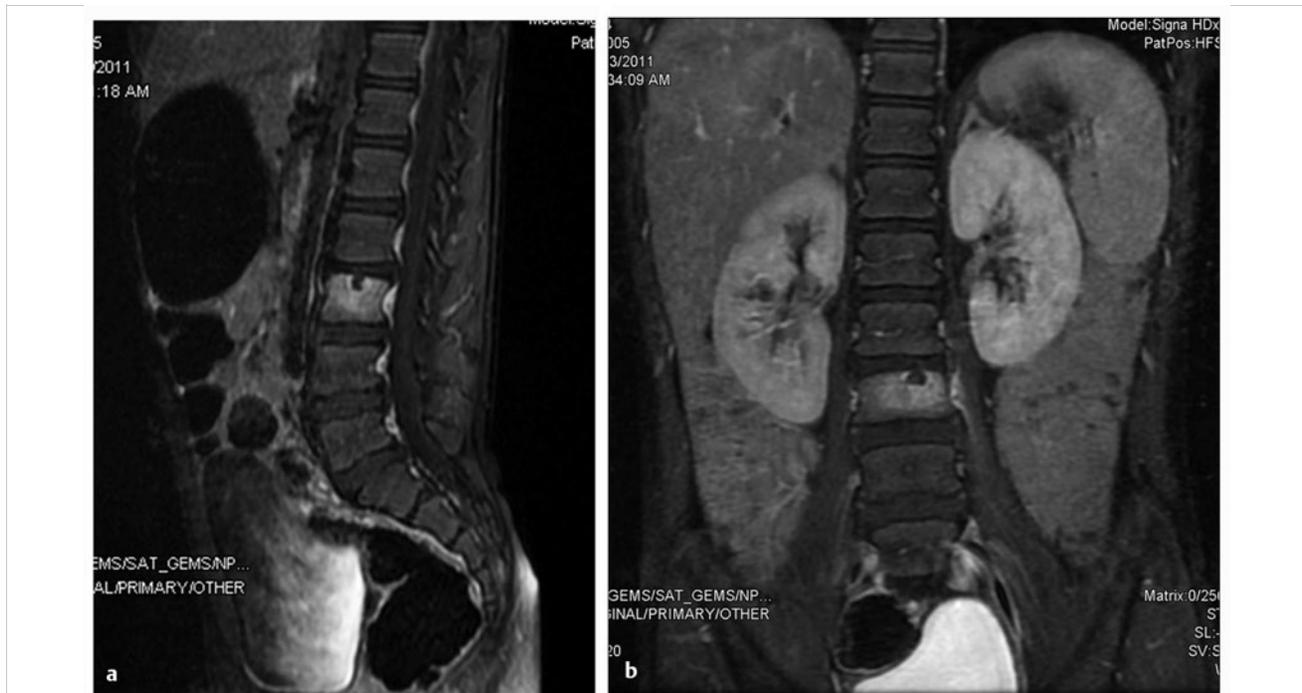

Fig. 81.2 (a,b) Pyogenic vertebral osteomyelitis. Six-year-old male had 2-week history of low back pain with sitting that resolves when lying down. There are no fevers. T1 post-contrast MRI discloses increased signal intensity within the L3 vertebral body with minimal signal change in the L2–3 disc. Blood cultures remained negative and patient did not respond to a 2-week course of IV Clindamycin. He was switched to Vancomycin and Rocephin with subsequent improvement.

obtained during the work-up reveal the causative organism, antibiotic treatment can be tailored appropriately. Current recommendations are for 6 weeks of intravenous antibiotic therapy with possible extension to 8 to 12 weeks depending on the relief of symptoms and reduction of the CRP and ESR.^{4,21,24,29}

81.1.3 Spinal Epidural Abscess

Epidural abscess was first described in 1761 and is recognized as a pyogenic infection of the epidural space. Spinal epidural abscess (SEA) may arise as a result of hematogenous seeding of the epidural space, of trauma or surgery, or of local extension of a soft-tissue abscess complicating PVO.³² It is now widely recognized that diskitis, PVO, and SEA may represent continuous points on a spectrum of infectious illness of the spine; however, the development of a SEA is a serious event that significantly increases the likelihood of permanent neurologic deficit.^{18,32} Neurologic injury may result from venous infarction due to local thrombophlebitis or from compression of the spinal cord or nerve roots caused by an inflammatory phlegmon.³³ The lumbar spine is preferentially involved. The diagnosis can be challenging because patients vary considerably in presentation.³⁴ An SEA may be a neurosurgical emergency, particularly in the setting of progressive neurologic deficit. However, the diagnosis of SEA is often delayed, and the neurologic deficit may be advanced and irreversible at the time of diagnosis. The reported

incidence of SEA ranges from 2 to 20 per 100,000, and the vast majority of cases occur in adults.^{32–34}

The majority of cases of SEA in children are individual case reports.^{18,35,36} SEAs in children are far less common than cranial epidural abscesses, which occur as a complication of common childhood illnesses, such as otitis media and sinusitis.^{37,38} In a 2001 review of SEA in children, Auletta and John noted that 26 pediatric patients with SEA had been reported in the medical literature, and they further characterized 8 children from their own institution. Most were boys without other illnesses, although 6 had concomitant PVO.³⁹ Observed similarities to adult SEAs were: rarity of the lesions, a prolonged symptomatic period before diagnosis, an etiology of hematogenous spread of infection, and easy detection with MR imaging. Important differences observed included an absence of predisposing conditions and less extensive abscesses in adults yet better outcomes in children.³² The location of the abscesses within the canal also differed significantly in that almost all pediatric SEAs were posterior, whereas a significant number of SEAs in adults were anterior.³⁹ Like the changes in the vascular anatomy of the disk space that impact the epidemiology of diskitis in adults and children, age-related differences in the vasculature of the epidural space may contribute to the preponderance of posteriorly located abscesses in children. These age-related changes in the vertebral vasculature may affect perfusion and the hematogenous distribution of infecting organisms.^{39,40}

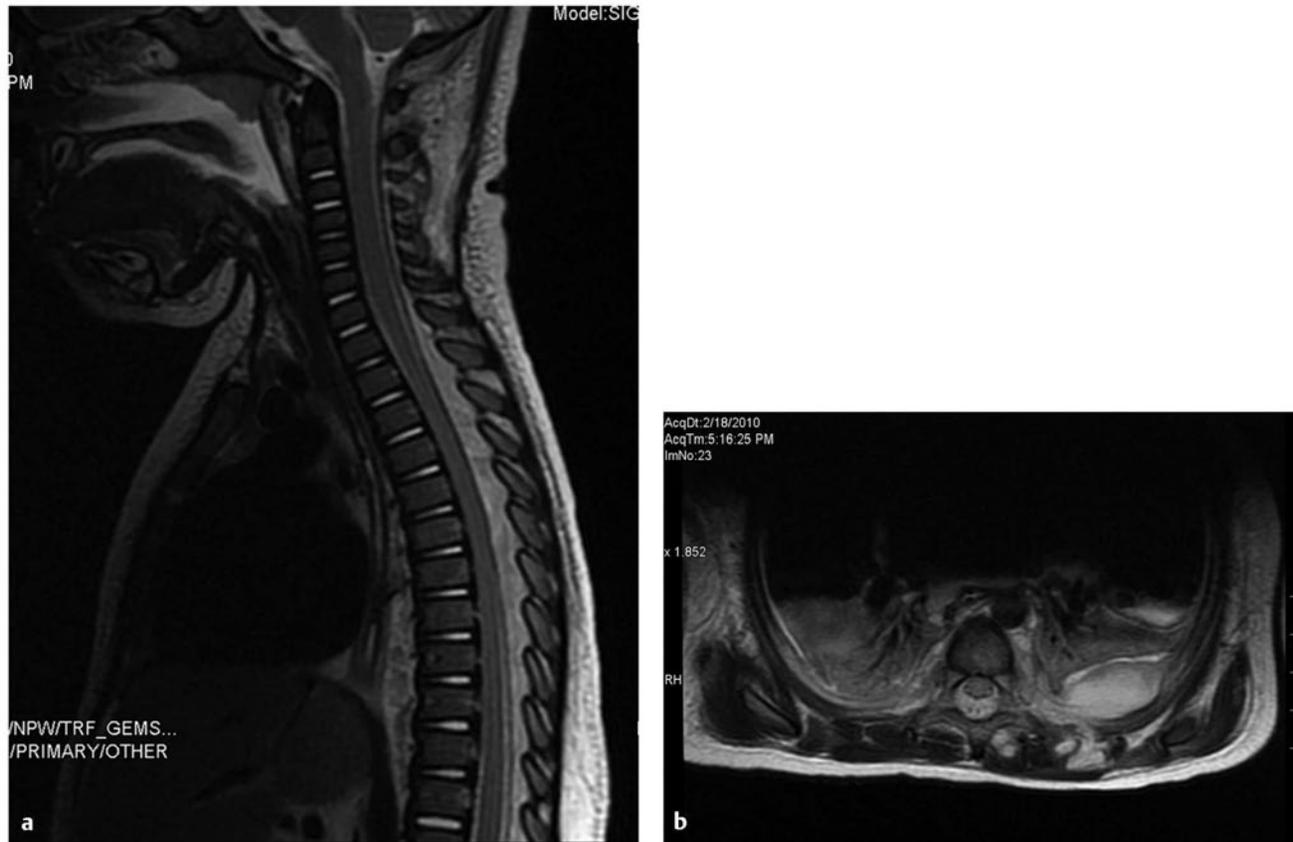

Fig. 81.3 (a,b) Spinal epidural abscess. T2 fat-suppressed MRI images of the spine in a 13-month-old female with MRSA sepsis and positive CSF cultures. There is a faint, dorsal epidural fluid collection from T1 through T9 with enhancement, a left pleural effusion, and paraspinal abscess. The patient was treated with 3 level laminoplasty with irrigation and debridement. She remained neurologically intact and resolved without sequelae.

Clinical Findings

The characteristic presentation of adults with the triad of progressive back pain, fever, and progressive neurologic deficit is widely reported in a minority of cases.³² In the large series of adult patients by Rigamonti and colleagues, 29% presented with limited or no back pain and no fever. Many patients had been seen multiple times before the diagnosis was made. Pain that was particularly sharp or lancinating and the presence of a neurologic deficit implicated SEA as more likely than PVO.⁴⁰ A meta-analysis of the comprehensive world literature identified 915 patients described with SEA. Most patients were in their mid 50s, but infants as young as 10 days old were described. Two-thirds of the patients had fever, and 71% reported back pain. Epidural catheters for regional anesthesia and spinal instrumentation were major iatrogenic sources of SEA.³²

Diagnostic Tests

Laboratory

Initial studies should include CBC with differential, ESR, CRP, and blood and urine cultures. As in PVO, the white cell count may be only minimally elevated (mean cell count, 15,000/mm³). The ESR and CRP are uniformly elevated in SEA.³² Culture data to guide antibiotic therapy can often be obtained by sampling during surgical decompression and evacuation.

Radiology

MR imaging is again the diagnostic modality of choice and is highly sensitive for SEA when performed with and without gadolinium contrast (► Fig. 81.3). Myelography via lumbar puncture is contraindicated because of the risk for seeding and secondarily infecting the subarachnoid space.

Treatment

Advances in imaging techniques, the development of highly effective antibiotic regimens, and advances in the understanding of spinal physiologic dynamics have fostered significantly better outcomes and prognosis for patients with SEA.³² Series from the 1950s and 1960s demonstrated combined rates of morbidity and mortality from SEA to be 34%, whereas those from the early 1990s showed that mortality had been halved, to 15%.^{32,33} Once an SEA is diagnosed, surgical intervention is virtually always indicated. Conservative management with antibiotics alone has been advocated in selected circumstances, but the possibility of sudden and irreversible neurologic decline despite antibiotic treatments warrants an aggressive surgical approach. In virtually all series, the best predictor of neurologic outcome in SEA is the patient's preoperative neurologic condition. A deficit that arises during antibiotic therapy and observation is unlikely to resolve. Situations in which surgical intervention might

not be appropriate include: 1) the presence of a very small amount of fluid in the epidural space (particularly if it extends over multiple levels) and no evidence of neurologic impairment, 2) the presence of complete neurologic deficit for longer than 3 days, 3) profound and overwhelming comorbidity adversely affecting the likelihood that the patient will survive an operation, and 4) refusal of the patient to consent to operative intervention.^{32,33,40}

Surgical goals include the evacuation of free pus from the epidural space, the sampling of infectious tissue to provide diagnostic cultures, and the maintenance and protection of spinal stability.^{34–36} In a patient with a free pyogenic infection, these goals can most often be accomplished via laminectomy. The purulent collection is almost uniformly posterior in all reported pediatric cases of SEA, but even when the collection is anterior, a laminectomy will often suffice to provide drainage and allow the sampling of material for diagnostic culture. Many SEAs involve multiple levels, and extended exposure is required to evacuate collections of pus. Surgical options include multiple-level laminectomies and alternating hemilaminotomies. An initial strategy incorporating alternating hemilaminotomies allows the surgeon to aspirate and vigorously irrigate the epidural space and still retain the posterior tension band that serves to prevent future slippage and the development of spondylolisthesis. If multiple-level hemilaminotomies (in which the spinous process and interspinous ligaments are spared) do not provide sufficient exposure to enable complete evacuation of the purulent material encountered in an SEA, then extension of the exposure to complete laminectomies can be undertaken at the surgeon's discretion. The use of surgical drains has not convincingly been shown to be superior to conventional closure alone.

The most common bacterial pathogens are *Staphylococcus* species—usually *S. aureus*. Non-iatrogenic (community-acquired) infections are usually broadly sensitive to methicillin (methicillin-sensitive *S. aureus*, or MSSA), whereas organisms resistant to methicillin (MRSA) are increasingly seen in situations of postoperative SEA. Antimicrobial chemotherapy should be administered at doses sufficient to achieve a tissue concentration adequate for elimination of the infection. Six weeks of intravenous antibiotics is usually considered the appropriate minimum duration of treatment. The course of recovery is monitored via the clinical signs (decreased pain and improved mobility) and laboratory values (normalized white blood cell count with decreasing CRP and/or ESR).^{33,34,40} Radiographic improvement is often delayed but can further document the regression and ultimate resolution of infection.

81.2 Granulomatous Infections

81.2.1 Tuberculosis of the Spine (Pott Disease)

Spinal TB (historically referred to as Pott disease after Percival Pott's classic description in 1786) occurs in approximately 1 to 3% of people who are infected with TB, yet the impact of tuberculous spondylodiskitis (TS) is immense because of the sheer number of people affected with TB.^{41–43} The prevalence of TB infection in the developing world is high, and a substantial resurgence of TB has occurred in the developed world in the last 30 years.⁴⁴ It is estimated that as many as 30 million people are

infected with TB throughout the world.⁴⁴ *M. tuberculosis* is transmitted via the inhalation of infectious particles and the establishment of pulmonary lesions. Hematogenous spread of microorganisms to the spine results in spinal tubercular osteomyelitis. Bovine TB (*Mycobacterium bovis*) is characteristically transmitted via the ingestion of tainted milk, so that the primary lesions are intestinal rather than pulmonary. Hematogenous spread is again implicated when *M. bovis* affects the spine.^{42,45} The axial skeleton is selectively but not exclusively involved and accounts for about 60% of all cases of tuberculous osteomyelitis.⁴² Typically, contiguous vertebral bodies and intervening disk spaces are affected. However, up to 10% of patients have multiple involved levels with intervening normal regions called skip lesions. There is a predilection for anterior vertebral body involvement of the thoracolumbar spine, although posterior elements may also be involved. Neurologic loss is observed in 10 to 40% of patients with TS.^{43,45,46}

In developed countries, public health initiatives and widespread effective antimicrobial regimens have significantly decreased the prevalence of TB (outside high-risk populations) and shifted the prevalence to adults. In the developing world, TS remains most common in the first three decades of life and is the leading cause of acquired paraplegia. Therefore, the epidemiology of spinal TB has evolved such that it is largely a disease of young persons in the developing world and nearly exclusively a disease of adults and the elderly in the developed world.^{46,47}

Although multiple classification systems have been proposed to characterize TS, the key distinctions are the formation of an epidural lesion, such as an abscess, granulation tissue, or a sequestrum, and whether the spine has been destabilized.^{41,43} Epidural masses, which are more common, may compress neurologic structures and adhere to the dura.^{48,49} Spinal cord injury occurs via either direct compression or venous infarction from local thrombophlebitis.

Direct invasion and destruction of a vertebral body is the other common pattern of TS and is the pattern most frequently seen in children. Such invasion leads to weakening of the bone, with the eventual compromise of columnar integrity and subsequent angulation and collapse. Severe kyphosis develops in about 3% of children with TS. Risk factors for severe deformity are young age (younger than 10 years), involvement of three or more vertebral bodies and a thoracic location.⁵⁰ Angulation may cause a point of focal compression where the spinal cord is draped over the apex. Irreversible myelopathic changes can occur subacutely or chronically. Spinal cord compression may also occur in the absence of collapse or epidural granulation when bony or cartilagenous sequestra formed as a result of bone infection and infarction is extruded into the spinal canal. The necrotic tissue becomes compressed and may be propelled laterally, anteriorly, or posteriorly into the spinal canal, with secondary compression of the adjacent thecal sac and spinal cord.⁴⁶

Clinical Findings

The presentation of TS depends upon the stage and form of the illness, which may differ significantly in developed and developing regions. In general, the initial presentation of TS reflects the status of the systemic illness, the bony insult, and the neurologic status.^{46,51} As with any infectious illness, there may be fever, diaphoresis (characteristically at night), secondary anorexia, and

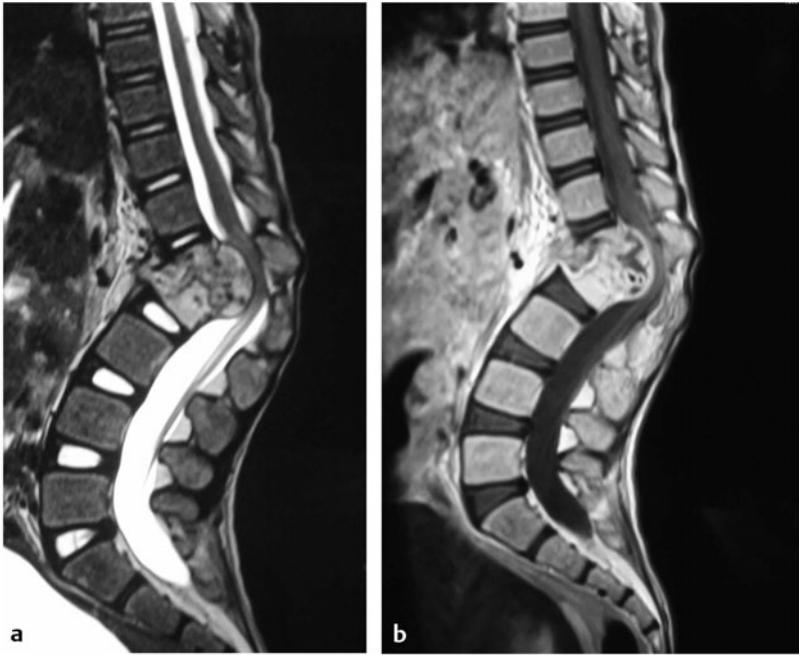

Fig. 81.4 (a,b) Lumbar spine tuberculosis. Eight-year-old, girl with chronic backache for last year. Physical examination: back deformity (low lumbar-dorsal kyphosis), painful on palpation, mild paraparesis 4-/5, sphincter dysfunction, hypotrophic lower limbs, hyperreflexia, and moderate spasticity. T1 and T2 MRI sequences reveal destruction of the vertebral body T12,L1,L2, respecting disk of T11 and L2, severe kyphoscoliosis with compression of the conus medullaris. There is a paravertebral abscess over both psoas. She went to surgery: laminectomy from T12, L1,L2, corpectomy of L1,L2 utilizing fibula as bone graft plus transpedicular screw placement in T11,T10 – L3,L4 plus rods and cross link. Previously, both paravertebral collections were evacuated to reveal caseum. Laboratory confirmed Koch bacille: Pott disease. (Case kindly provided by Dr. José Efraín García Reyes, Hospital Nacional Guillermo Almenara Irigoyen-Lima, Peru.)

weight loss.^{42,46} In children in developed regions, TS is rare and is associated with immune compromise, often presenting early in the course of the illness.^{45,52} Despite the early presentation, the diagnosis is often substantially delayed because of the lack of specificity of the presenting signs and symptoms. Clinical symptoms in children are characteristically insidious but may include back pain, malaise, and fever, in addition to neurologic decline in the form of paraparesis, sensory disturbance, or bowel and bladder dysfunction.^{41,45,48} Overall, neurologic involvement is reported in from 10 to 40% of cases but appears heavily weighted toward adults. Back pain is usually a predominant symptom, and for an experienced examiner, the degree of spasm and rigidity that accompany the pain is pathognomonic.^{45,49} In undeveloped regions, late presentation with a characteristic soft-tissue mass, a gibbus or kyphotic angulation, and a long history of back pain is more common.⁴⁵

Diagnostic Studies

Laboratory

Serologic investigation in active TB typically demonstrates a moderately elevated white blood cell count, an elevated ESR, and a mildly diminished hemoglobin concentration. Skin studies (Mantoux test) are often falsely negative if the patient is immunocompromised. Furthermore, BCG immunization, which is widely conducted in the developing world as vaccination for TB, has a success rate of approximately 80% in imparting immune resistance but uniformly causes a positive Mantoux test. The culture of acid-fast bacilli takes 6 to 8 weeks, but polymerase chain reaction specific for *Mycobacterium* DNA sequences is rapid and accurate when available.

Radiology

Plain radiographs first show disk space narrowing and end plate destruction, which may progress to anterior wedging or

vertebral angulation and collapse (► Fig. 81.4, ► Fig. 81.5). Pulmonary lesions may be demonstrated in 40 to 50% of cases, and spinal bony involvement is absent in 12 to 15%. MR imaging is now widely and rapidly available in developed countries and is the preferred examination. MR imaging characteristically demonstrates the full extent of TS, including epidural granulation tissue or abscess, adjacent soft tissue abscesses, and inflammation of the vertebral body or posterior elements. Characteristically, T1-weighted images show decreased signal from the affected marrow, decreased disk height, and involvement of the paraspinous soft tissue. T2 images show increased signal throughout the bone and adjacent soft tissue. A favorable response to treatment is best followed on T1-weighted images, on which an increase in signal intensity will be observed when images obtained after treatment are contrasted with previous images for the same patient.^{47,52}

In many developing countries, CT is the available imaging modality of choice. CT can quite adequately demonstrate the multiple manifestations of TS, including vertebral body compromise, paravertebral abscesses, and posterior element involvement, in addition to the extent of epidural involvement. Furthermore, CT may detect bone destruction earlier.³⁰

Treatment

The treatment and management of TS depend upon the presentation of the patient and must be individualized. If TS is diagnosed early, whereby the neurologic examination is intact and there is no bony destruction, then the patient is treated medically with or without immobilization. The greatest concern regarding conservative treatment is the real incidence of progressive kyphosis. The immobilization of patients not requiring surgical intervention is a controversial topic. Bed rest has known serious complications, but because of concern for vertebral collapse, physicians are reluctant to allow weight bearing in infected individuals.

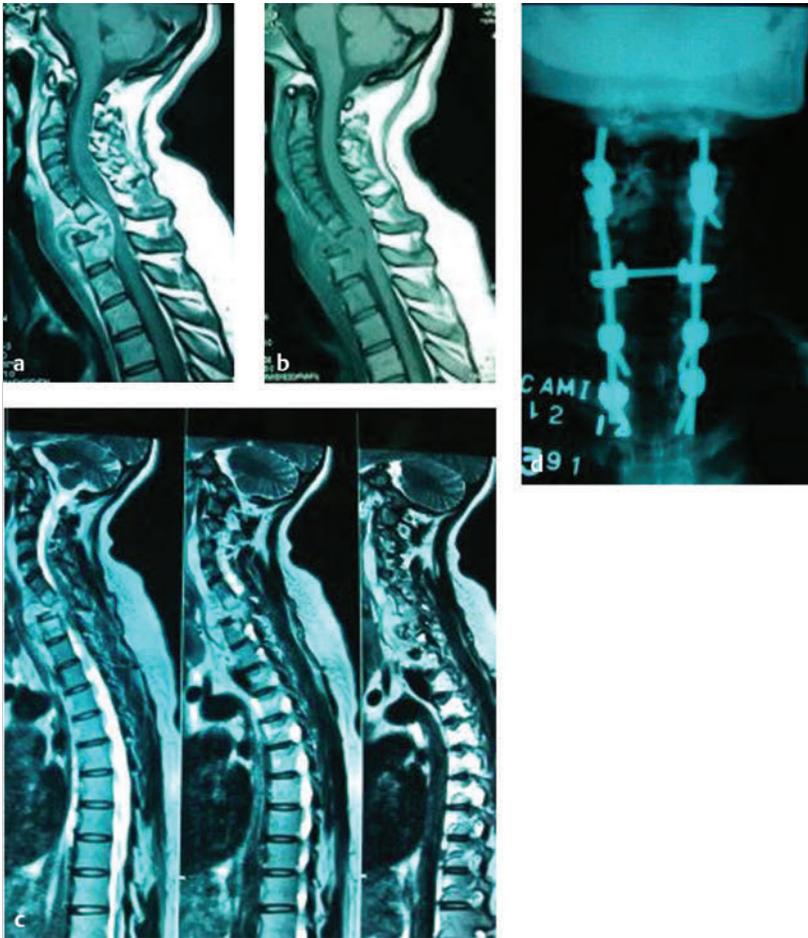

Fig. 81.5 (a–d) Cervical spine tuberculosis. Twenty-four-year-old male with neck pain, moderate quadriplegia, and loss of sphincter function. Contrast-enhanced sagittal MRI T1 sequences reveal destruction of C7 vertebral body with loss of vertebral height, retropulsion of inflammatory mass, cord compression, and kyphotic angulation. Surgical correction with vertebrectomy and multiple level posterior fusion. (Case kindly provided by Dr. José Efraín García Reyes, Hospital Nacional Guillermo Almendra Irigoyen-Lima, Peru.)

The Medical Research Council of England reported good results when antimicrobial chemotherapy was combined with ambulation in children. Medical treatment typically involves at least three agents for 6 months.^{46,53} Introduced in 1947, streptomycin was the first antimicrobial to show efficacy against acid-fast bacilli. A common regimen consists of rifampin, isoniazid, ethambutol, and pyrazinamide for 2 months, followed by rifampin and isoniazid for a variable period of 7 to 9 additional months.⁵³

Various surgical approaches for TS have been debated in the medical literature.^{51,54,55} Limited surgery consists of laminectomy, whereas a more radical operation involves an anterior approach with complete resection of infected and compromised vertebral bodies and secondary reconstruction with a bone graft (the Hong Kong procedure).^{55,56} Several modifications to the Hong Kong procedure have recently been advocated that center on the incorporation of internal fixation with instrumentation.^{57,58} The two conceptually divergent approaches are antimicrobial chemotherapy (either with or without bed rest) and radical surgery (Hong Kong procedure or variant). The Medical Research Council of the United Kingdom addressed this controversy with a prospective study that demonstrated comparable rates of long-term disease control and eradication in the two treatment groups (85 and 89%, respectively) but reduced long-term deformity in the patients treated with radical surgery.⁵⁵

There appears to be consensus that surgery is indicated in the following situations: (1) there is neurologic compromise

that may be arrested, (2) kyphosis or angulation is progressive or severe, (3) pain is severe and associated with kyphosis or collapse, (4) there is evidence of progression of disease while the patient is on optimized medical therapy, and (5) the diagnosis is in doubt.^{54–56} It is recognized that children have a greater potential to develop kyphosis with growth over time.^{57,58} Surgical goals include the decompression of neural elements, stabilization of columnar spinal stability, and correction of any kyphosis that may be present.

Laminectomy is the preferred procedure when the primary problem is a dorsal epidural collection of granulation material and no kyphosis is present.⁵¹ Laminectomy is insufficient when the patient has significant vertebral body disease because of the potential for delayed kyphosis and the inability to address any ventral spinal cord compression that may be present. Posterior instrumented fusion can meaningfully augment stabilization but can do little to correct kyphosis. Instrumented fixation and stabilization can be undertaken in a field actively infected with TB without any apparent elevation in the risk for delayed infection.⁵¹

Vertebral body involvement at the time of diagnosis is common, and the presence of, or risk for, the development of kyphosis is central to guiding surgical decision making. An anterior decompression via a transthoracic, transpleural, or retroperitoneal approach that is augmented with a bone graft is highly effective at restoring sagittal balance, preventing further kyphosis, and protecting the spinal cord.^{55,56} Posterior instru-

mented fusion can be done at same time or in a staged fashion. More extensive surgery appears to be more effective in correcting the degree of deformity in children, but only a very limited experience in young children has been reported to date.^{55,56,58}

81.2.2 Tuberculosis of the Craniovertebral Arch

This rare variant of TS occurs frequently in developing countries, but infrequently in the developed world. It is associated with severe complications because of the involvement of ligaments at the craniocervical junction, with potential for ligamentous laxity and secondary instability. Atlantoaxial dislocation, translocation of the dens, and cervicomedullary compression have been described. The diagnosis is obtained on the basis of CT (or rarely MR imaging), which reveals subluxation of the C1–2 elements. Traction, immobilization, and antimicrobial therapy form the basis of treatment.⁵⁹

81.2.3 Brucellosis

In areas where it is endemic (South America, central Asia, the Middle East, and the Mediterranean region), brucellosis is a public health problem, and it is the most common zoonosis in humans.⁶⁰ The species most commonly seen are *Brucella abortus*, *Brucella melitensis*, and *Brucella suis*. All are intracellular pathogens. The incidence of systemic brucellosis is increasing, and 20 to 25% of cases involve children.⁶⁰ Transmission occurs from infected animals to humans via contact with body fluid (in adults) or the consumption of raw milk or milk products (in children). Cutaneous, hematologic, and respiratory complications are most common in children, whereas osteoarticular and cardiac complications are most frequent in adults.

Signs and symptoms are not specific and most commonly consist of arthralgia, fever, night sweats, and weight loss, but the disease can have a very wide clinical spectrum.⁶⁰ Spinal brucellosis resembles PVO and may be present focally or diffusely.²⁹ Focal disease occurs in the anterior end plate, whereas diffuse disease involves multiple levels and the intervening disk space. The diagnosis is based upon the identification of possible exposure, clinical features suggestive of brucellosis, and serologic tests with or without blood cultures. The sensitivity of serologic tests is 65 to 95%, but the specificity is low because of the presence of antibodies in the bloodstream in regions where brucellosis is endemic. Radiographically, there is characteristically sparing of the vertebral body and an absence of deformity.²⁹ Treatment requires at least two antibiotics (tetracycline, doxycycline, rifampin) for a duration of 6 weeks.

81.3 Conclusion

Infections of the spinal axis are an uncommon but important set of disorders that may be classified as pyogenic (acute humoral immunity) or granulomatous (chronic inflammation). Three patterns of pyogenic disease can be recognized: diskitis, vertebral osteomyelitis, and spinal epidural abscess. Diskitis does not compromise neurologic function, requires antibiotic treatment and immobilization, and has an excellent prognosis. Insufficiently treated or untreated diskitis may either resolve

spontaneously or go on to cause vertebral osteomyelitis or SEA. Vertebral osteomyelitis varies very widely in severity, carries a more serious prognosis, and requires prolonged antibiotic treatment. SEA threatens neurologic function via compression and local thrombophlebitis, which often lead to acute and irreversible deficits if timely surgical evacuation is not undertaken.

Infections that preferentially affect the vertebral body, such as tuberculosis, often compromise the integrity of the vertebral body and lead to kyphosis, deformity, and collapse. Any of these may acutely or chronically impair spinal cord function and cause permanent neurologic dysfunction. Surgery is indicated for a patient with severe or progressive kyphosis, neurologic decline, or disease progression while on appropriate medical therapy. Laminectomy, bracing, and antibiotics are just as effective as radical vertebrectomy with reconstruction for local disease control, but vertebrectomy is associated with better long-term correction of kyphosis and angulation.

Each of these entities presents challenges to timely diagnosis because of the insidious and nonspecific nature of the symptoms and the frequent presence of other important comorbid conditions. Therefore, a high index of awareness of these conditions will help the astute clinician avoid the delays in diagnosis and intervention that have been typical for this important group of illnesses.

Pearls

1. Diskitis must be suspected in any toddler who refuses to sit or stand. It is highly responsive to immobilization and a limited course of antibiotics.
2. PVO is characterized by a clinical appearance similar to that of diskitis, but the child appears sicker overall and has fever. Treatment with antibiotics for a minimum of 6 weeks is required, and both the clinical course and the laboratory values (CRP and ESR) must be followed to judge the duration of therapy. MR imaging allows a rapid, certain diagnosis and the initiation of therapy.
3. Tuberculous osteomyelitis is a disease of the young (first three decades) in the developing world and a disease of adults with significant comorbidities in developed regions.
4. Tuberculous osteomyelitis may compromise neurologic function via compression by an epidural mass or vertebral body collapse with angulation and kyphosis.
5. Surgical intervention for tuberculous osteomyelitis may be either via laminectomy with antibiotics and bracing or via anterior vertebrectomy and reconstruction. The two approaches do not differ in efficacy for local disease control, but vertebrectomy is associated with a reduced rate of complications related to kyphosis and angulation.

Neuroanesthesia

82 Pediatric Neuroanesthesia

82 Pediatric Neuroanesthesia

Sulpicio G. Soriano and Mark A. Rockoff

Advances in pediatric neurosurgery and anesthetic techniques have dramatically improved the outcome in infants and children afflicted with surgical lesions of the central nervous system (CNS). However, the physiologic and developmental differences inherent in pediatric patients present challenges to neurosurgeons and anesthesiologists alike. The aim of this chapter is to highlight these age-dependent aspects of the perioperative management of the pediatric neurosurgical patient.

82.1 Developmental Considerations

Age-dependent differences in cerebrovascular physiology and cranial bone development have a significant impact on the perioperative management of neurosurgical patients. Cerebral blood flow is coupled tightly to metabolic demand, and both increase proportionally immediately after birth. Estimates from animal studies place the autoregulatory range of blood pressure in a normal newborn between 20 and 60 mm Hg.¹ This is consistent with the relatively low cerebral metabolic requirements and blood pressure during the perinatal period. Importantly, the slope of the autoregulatory curve drops and rises significantly at the lower and upper limits of the curve, respectively (► Fig. 82.1). This narrow range, with sudden hypotension and hypertension at either end of the autoregulatory curve, places the neonate, especially when premature, at risk for cerebral ischemia and intraventricular hemorrhage, respectively. Generally, full-term healthy infants have the ability to autoregulate their cerebral circulation, but premature neonates do not.² Furthermore, high-risk term and premature neonates do not exhibit intact cerebral autoregulation.³ Therefore, tight blood

pressure control is essential in the management of neonates to minimize both cerebral ischemia and intraventricular hemorrhage. On studies performed with noninvasive transcranial Doppler technology, the lower limits of cerebral autoregulation appear to be equivalent among older and younger children.⁴ However, children younger than 2 years old have lower baseline mean arterial pressures; they have less autoregulatory reserve and can theoretically be at greater risk for cerebral ischemia. Another developmental difference between an adult and a pediatric patient is the larger percentage of cardiac output that is directed to the brain in a child because the head of an infant or child accounts for a larger percentage of the body surface area and blood volume (► Fig. 82.2), resulting in proportionally greater blood loss and more significant hemodynamic instability in a small child than in an adult.

The infant's cranial vault is also in a state of development. The open fontanelles and cranial sutures result in a compliant intracranial space (► Fig. 82.3). The mass effect of a slow-growing tumor or insidious hemorrhage is often masked by a compensatory increase in intracranial volume accompanied by head growth. As a result, infants presenting with signs and symptoms of intracranial hypertension frequently have fairly advanced pathology. However, acute increases in cranial volume due to massive hemorrhage or an obstructed ventricular system will lead to life-threatening intracranial hypertension.⁵

Age-dependent variations also have pharmacologic and physiologic consequences for the perioperative course of neonates and infants. Total body water decreases from 85% in premature infants to 65% in adults, while body fat content increases from less than 1% in premature infants to 15% in term infants and 35% in adults. Total protein follows a similar trend. Therefore, hydrophilic drugs have more binding sites and hydrophobic

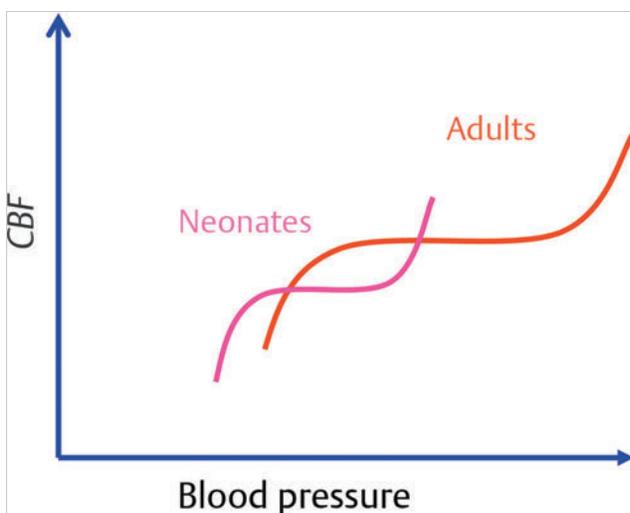

Fig. 82.1 Autoregulation of cerebral blood flow (CBF) in children. The slope of the autoregulatory curve drops and rises significantly at the lower and upper limits of the curve, respectively, and is shifted to the left in neonates and small children.

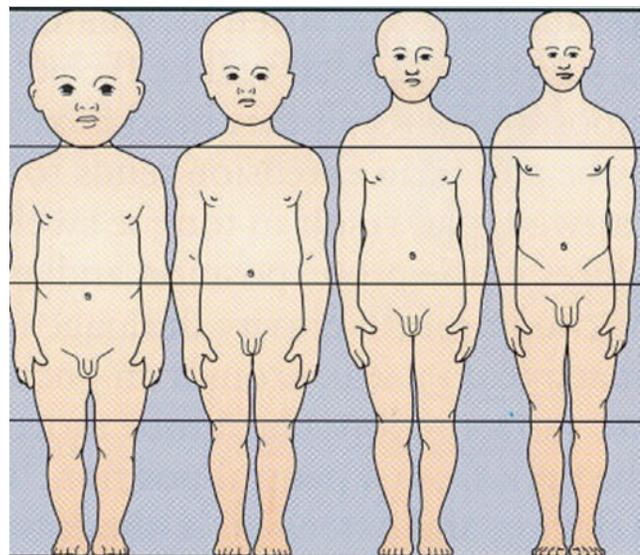

Fig. 82.2 Head size. The head size and surface area are proportionally greater in an infant than in an adult.

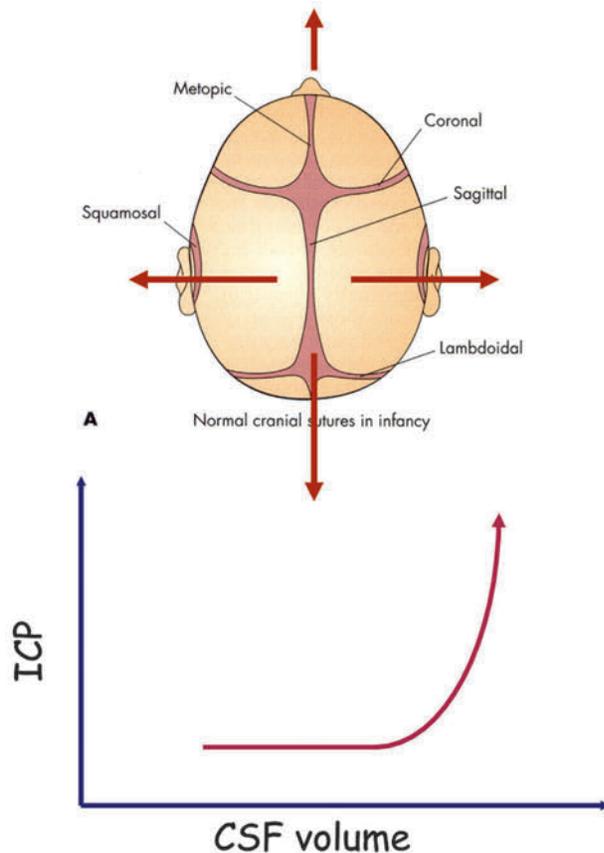

Fig. 82.3 (a,b) Effect of open cranial sutures and fontanel in neonates and infants. Initially, the compliant skull of the neonate will minimize insidious increases in intracranial volume. However, acute increases in intracranial volume (hemorrhage and obstructed ventriculoperitoneal shunt) will lead to rapid rises in intracranial pressure (ICP). CSF, cerebrospinal fluid.

drugs have fewer binding sites in infancy. The immature renal system is characterized by a decreased glomerular filtration rate and concentrating ability. These changes result in the diminished excretion of saline and water and limit the neonate's ability to compensate for fluctuations in fluid and solute loads. Furthermore, drugs that are excreted primarily in the urine may have a prolonged half-life. Hepatic function is also diminished in neonates, and the metabolism of drugs may be delayed because of the decreased activity of hepatic enzymes. The constellation of these factors should prompt the clinician generally to decrease the dose and frequency of administration of drugs given to the newborn.

82.2 Preoperative Evaluation and Preparation

Preparation of the pediatric patient for anesthesia and surgery is frequently overlooked in the perioperative period. Given the systemic effects of general anesthesia and the physiologic stress of surgery, an organ system review is essential for anticipating potential physiologic derangements and coexisting disease

Table 82.1 General perioperative concerns in infants and children

Condition	Anesthetic implications
Congenital heart disease	Hypoxia, arrhythmias, and cardiovascular instability. Paradoxical air emboli
Prematurity	Postoperative apnea
Gastrointestinal reflux	Aspiration pneumonia
Upper respiratory tract infection	Laryngospasm, bronchospasm, hypoxia, pneumonia
Craniofacial abnormality	Difficulty with airway management

states that may place the patient at increased risk for perioperative complications.⁶ General perioperative concerns in infants and children are listed in ► Table 82.1. Preoperative laboratory testing should be tailored to the proposed neurosurgical procedure. Given the risk for significant blood loss associated with surgery, a hematocrit in addition to prothrombin time and partial thromboplastin time tests, should be obtained to uncover any insidious hematologic disorder. Serum thyroid hormone levels should be obtained for patients with suprasellar pathology. Type- and cross-matched blood should be ordered before all craniotomies. ► Table 82.2 matches special concerns in pediatric patients with specific neurologic problems. Subspecialists in these areas may be needed to help optimize the patient's condition before surgery and to assist in postoperative management.

Closed-claim analysis studies have revealed that neonates and infants are at higher risk for morbidity and mortality than any other age group.^{7,8} Respiratory- and cardiac-related events account for a majority of these complications. However, no studies indicate any difference in the influence of neurosurgical disease on the morbidity and mortality of pediatric patients. Given the urgent nature of many pediatric neurosurgical procedures, a thorough preoperative evaluation may be difficult. However, a complete airway examination is essential because some craniofacial anomalies may require specialized techniques to secure the airway.⁹ Most cardiac morbidity due to congenital heart disease occurs during the first year of life. Congenital heart disease may not be apparent immediately after birth. Therefore, echocardiography can be helpful in the assessment of the cardiovascular system, especially in the neonate, and a pediatric cardiologist should evaluate a patient with suspected problems to help optimize cardiac function before surgery.

Anesthetic drug-induced neurotoxicity has been the focus of extensive preclinical and clinical research.¹⁰ It has been clearly demonstrated in fetal and neonatal laboratory animals that all classes of anesthetic drugs lead to a dose- and duration-dependent increase in neurodegeneration. However, retrospective epidemiologic reports have been inconclusive. Therefore, parents should be reassured that vital surgery cannot be performed without adequate anesthesia, and that the likelihood of the neurodegenerative effects of anesthetic drugs is insignificant in comparison with delaying or withholding anesthesia and surgery.

Separation from parents and perioperative anxiety play a significant role in the care of the pediatric neurosurgical patient. These issues are related to the cognitive development and age

Table 82.2 Common perioperative concerns for infants and children with neurologic problems

Condition	Anesthetic implications
Denervation injuries	Hyperkalemia after succinylcholine Resistance to nondepolarizing muscle relaxants Abnormal response to nerve stimulation
Chronic anticonvulsant therapy	Hepatic and hematologic abnormalities Increased metabolism of anesthetic agents
Arteriovenous malformation	Potential congestive heart failure
Neuromuscular disease	Malignant hyperthermia Respiratory failure Sudden cardiac death
Ketogenic diet and/or topiramate therapy	Chronic metabolic acidosis
Chiari malformation	Apnea Aspiration pneumonia
Hypothalamic/pituitary lesions	Diabetes insipidus Hypothyroidism Adrenal insufficiency

Table 82.3 Developmental factors affecting the pediatric patient in the perioperative period

Age group	Concerns
Infants (0 to 9 months)	None, will separate easily from parents
Preschoolers (9 months to 5 years)	Stranger anxiety, difficulty with parental separation
Grade-schoolers (6 to 12 years)	Fear of needles and pain
Adolescents (> 12 years)	Anxiety about surgery and self-image

of the child (► Table 82.3). Preoperative sedatives given before the induction of anesthesia can ease the transition from the preoperative holding area to the operating room.¹¹ Midazolam administered orally is particularly effective in relieving anxiety and producing amnesia. If an indwelling intravenous (IV) catheter is in place, midazolam can be slowly titrated to achieve sedation.

Preoperative fasting regimens have dramatically evolved over the years and vary according to local preferences.¹² The purpose of limiting oral intake is to minimize the risk for pulmonary aspiration of the gastric contents. However, prolonged fasting periods can result in both hypovolemia and hypoglycemia, which, in turn, can lead to hemodynamic and metabolic instability during anesthesia. Although the scientific validity of many recommendations has not been investigated, a common guideline is shown in ► Table 82.4.

82.3 Intraoperative Management

82.3.1 Induction of Anesthesia

The patient's neurologic status and coexisting abnormalities will dictate the appropriate technique and drugs for the induction of anesthesia. Often, general anesthesia can be established

Table 82.4 Common fasting guidelines for pediatric patients

Fasting time (h)	Oral intake
2	Clear liquids
4	Breast milk
6	Formula
8	Solid food

with the inhalation of sevoflurane and nitrous oxide with oxygen. A nondepolarizing muscle relaxant is then administered after IV access has been established to facilitate intubation of the trachea. Alternatively, if the patient already has an IV catheter, anesthesia can be induced with a sedative-hypnotic drug, such as propofol (3 to 4 mg/kg). These IV agents rapidly induce unconsciousness and can blunt the hemodynamic effects of tracheal intubation. Furthermore, they have minimal effects on cerebrovascular hemodynamics and maintain tight coupling of the cerebral blood flow and cerebral metabolic rate. Patients at risk for aspiration pneumonitis should undergo a rapid-sequence induction of anesthesia with propofol, immediately followed by the administration of a rapidly acting muscle relaxant and the application of cricoid pressure. Rocuronium can be used when succinylcholine is contraindicated, such as for patients with spinal cord injuries or paretic extremities. In these instances, succinylcholine can result in sudden, catastrophic hyperkalemia. Etomidate and ketamine are frequently used to induce anesthesia in hemodynamically compromised patients because these drugs are less likely to cause hypotension than is propofol. However, CNS excitation and increased intracranial pressure (ICP) have been associated with these drugs, respectively, and they may not be appropriate for some neurosurgical patients.

82.3.2 Airway Management

Developmental features of the airway anatomy have a significant impact on the management of the pediatric airway. The

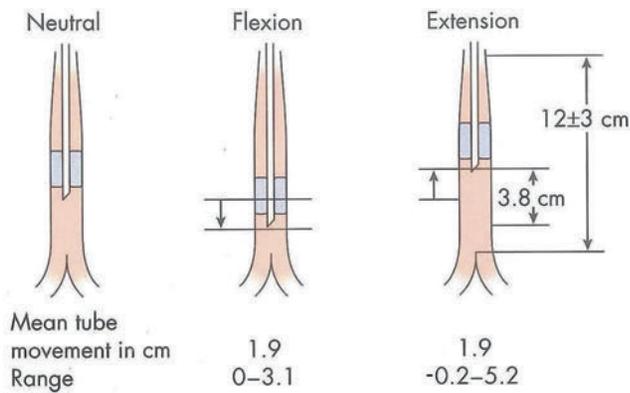

Fig. 82.4 Effect of head flexion and extension on endotracheal tube position.

infant's larynx is funnel-shaped and narrowest at the level of the cricoid ring. This feature places the infant at risk for subglottic obstruction secondary to mucosal swelling after prolonged endotracheal intubation with a tightly fitting endotracheal tube. Because the trachea is relatively short in the neonate and infant, an endotracheal tube can easily migrate into a main bronchus when the head is flexed, as is done during a suboccipital approach to the posterior fossa or the cervical spine (► Fig. 82.4). Therefore, great care should be devoted to ensuring proper positioning of the endotracheal tube during tracheal intubation, and the anesthesiologist should auscultate both lung fields to rule out inadvertent intubation of a main bronchus after final positioning of the patient for the procedure. Nasotracheal tubes are best suited for situations in which the patient will be prone.¹³ Furthermore, orotracheal tubes can kink at the base of the tongue when the head is flexed, resulting in airway obstruction and direct pressure injury to the tongue.

82.3.3 Positioning

Patient positioning for surgery requires careful preoperative planning to allow both the neurosurgeon and the anesthesiologist adequate access to the patient. ► Table 82.5 describes various surgical positions and their physiologic sequelae. The prone position is commonly used for posterior fossa and spinal cord surgery, although the sitting position may be more appropriate for obese patients, who may be difficult to ventilate in the prone position because of increased intra-abdominal pressure (► Fig. 82.5). In addition to the physiologic sequelae of this position, a whole spectrum of compression and stretch injuries have been reported. Padding under the chest and pelvis can support the torso. It is important to ensure free abdominal wall motion because increased intra-abdominal pressure can impair ventilation, cause vena caval compression, and increase epidural venous pressure and bleeding. Soft rolls are generally used to elevate and support the lateral chest wall and hips to minimize the increase in abdominal and thoracic pressure. In addition, they allow a Doppler probe to be placed on the chest without causing direct pressure injury. Many neurosurgical procedures are performed with the head slightly elevated to facilitate venous and cerebrospinal fluid (CSF) drainage from the surgical site. However, superior sagittal sinus pressure decreases with

Table 82.5 Physiologic effects of patient positioning

Position	Physiologic effect
Head elevated	Enhanced cerebral venous drainage Decreased cerebral blood flow Increased venous pooling in lower extremities Postural hypotension
Head down	Increased cerebral venous and intracranial pressure Decreased functional residual capacity (lung function) Decreased lung compliance
Prone	Venous congestion of face, tongue, and neck Decreased lung compliance Increased abdominal pressure possibly leading to vena caval compression
Lateral decubitus	Decreased compliance of downside lung

Fig. 82.5 Sitting position.

increasing head elevation; this increases the likelihood of venous air emboli (VAE).¹⁴ Extreme head flexion can cause brainstem compression in patients with posterior fossa pathology, such as mass lesions or a Chiari malformation. However, significant rotation of the head can impede venous return through the jugular veins and lead to impaired cerebral perfusion, increased ICP, and venous bleeding.

82.3.4 Vascular Access

Because of the limited access to the patient (especially small children) during neurosurgical procedures, ensuring optimal IV access is mandatory before the start of surgery. Typically, two large-bore venous cannulas are sufficient for most craniotomies. Should initial attempts fail, central venous cannulation may be necessary. Use of the femoral vein avoids the risk for pneumothorax associated with subclavian catheters and does not interfere with cerebral venous return, as may be the case with jugular catheters. Furthermore, femoral catheters are more easily accessible to the anesthesiologist during operations on the head. Because significant blood loss and hemodynamic instability can occur during craniotomies, cannulation of the radial artery provides direct blood pressure monitoring and

sampling for blood gas analysis. Other useful arterial sites in infants and children include the dorsalis pedis artery and posterior tibial artery.

82.3.5 Maintenance of Anesthesia

Several classes of drugs are used to maintain general anesthesia. Each has distinct characteristics that make it potentially appropriate for neurosurgery. Potent, volatile anesthetic agents (i.e., sevoflurane, isoflurane, and desflurane) are administered by inhalation. Sevoflurane has virtually replaced halothane as the principal agent for the induction of anesthesia in infants and children.¹⁵ It rapidly induces anesthesia and minimally depresses the cardiovascular system.¹⁶ Changing the inspired concentration of the drug can rapidly alter anesthetic depth. These inhaled drugs are potent cerebrovascular dilators and cerebral metabolic depressants, two qualities that can lead to a dose-dependent uncoupling of cerebral metabolic supply and demand and to increased cerebral blood volume and ICP. Moreover, their use can be associated with a significant decrease in cerebral perfusion pressure that is due primarily to a dose-dependent reduction in arterial blood pressure.¹⁷ Given these issues, volatile anesthetics are rarely used as the sole anesthetic for neurosurgery.

IV anesthetics are categorized as sedative-hypnotic or opioid. These drugs are also potent cerebral metabolic depressants but do not cause cerebral vasodilation. Therefore, they are closer to “ideal” anesthetics. Fentanyl is the opioid most commonly used in this setting. The context-sensitive half-life of fentanyl and sufentanil increase with repeated dosing or prolonged infusion, and the drugs require hepatic metabolism, which is immature in neonates. As a result, their narcotic effects, such as respiratory depression and sedation, may be prolonged. Remifentanyl is a unique opioid that is rapidly cleared by plasma esterases. Therefore, when administered at a rate of 0.2 to 1.0 $\mu\text{g}/\text{kg}$ per minute, it is an ideal opioid for rapid emergence from anesthesia.^{18,19} However, this rapid recovery is frequently accompanied by delirium and inadequate analgesia.^{20,21}

Nevertheless, the choice of agents for the maintenance of anesthesia has been shown not to affect the outcome of neurosurgical procedures when they are properly administered.²² The most frequently used anesthetic technique during neurosurgery consists of an opioid (fentanyl or remifentanyl) along with inhaled nitrous oxide (70%) and low-dose (0.2 to 0.5%) isoflurane. The incidence of awareness under anesthesia has been reported to be 0.8%, a value higher than that in adults.²³ Processed electroencephalographic algorithms have been advocated to measure the depth of anesthesia. However, their utility in children younger than 3 years is still in question.²⁴ Deep neuromuscular blockade with a nondepolarizing muscle relaxant is maintained to avoid patient movement and to minimize the amount of anesthetic agents needed. Patients receiving chronic anticonvulsant therapy will require larger doses of muscle relaxants and narcotics because of the induced enzymatic metabolism of these agents²⁵ (► Fig. 82.6). Muscle relaxants should be withheld or their effects permitted to wear off when an assessment of motor function during neurosurgery is planned.

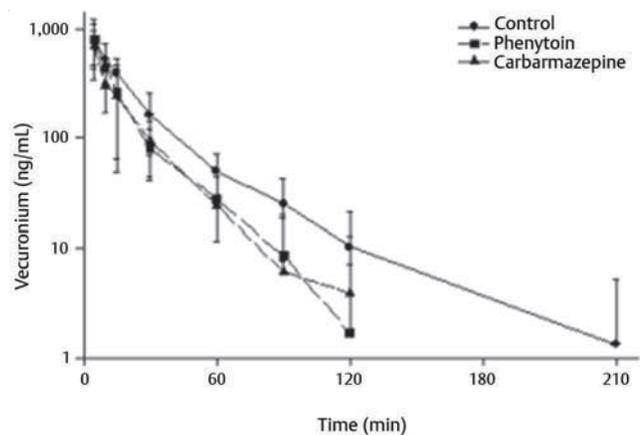

Fig. 82.6 Effect of chronic anticonvulsant therapy on the half-life of the muscle relaxant vecuronium. Vecuronium plasma concentrations are plotted against time after a single bolus dose of vecuronium ($0.15 \text{ mg} \cdot \text{kg}^{-1}$). Mean \pm standard deviation is plotted for all three groups.

Table 82.6 Estimated blood volume in children

Age	Estimated blood volume (mL/kg)
Preterm neonates	100
Full-term neonates	90
Children 1 year or younger	80
Children 1 to 12 years	75
Adolescents and adults	70

82.3.6 Intraoperative Fluid and Electrolyte Management

Hemodynamic stability during intracranial surgery requires the careful maintenance of intravascular volume and electrolytes. Preoperative fluid restriction and/or diuretic therapy may lead to blood pressure instability and even cardiovascular collapse if sudden blood loss occurs during surgery. Therefore, normovolemia should be maintained throughout the procedure. Estimation of the patient's blood volume is essential in determining the amount of allowable blood loss and when blood will need to be transfused. Blood volume depends on the age and size of the patient, as delineated in ► Table 82.6. Normal saline is commonly used as the maintenance fluid during neurosurgery because it is mildly hyperosmolar (308 mOsm/kg) and should minimize cerebral edema. However, rapid infusion of large quantities of normal saline ($>60 \text{ mL}/\text{kg}$) can be associated with hyperchloremic acidosis.²⁶ Given the relatively large blood volume of the neonate and infant, the maintenance rate of fluid administration depends on the weight of the patient (► Table 82.7). Because significant blood loss is likely to occur during most craniotomies in infants and children, the maximum allowable blood loss should be determined in advance to know when blood should be transfused. However, there are no guidelines

regarding the threshold for transfusing blood, and the decision to transfuse should be dictated by the type of surgery, the underlying medical condition of the patient, and the potential for additional blood loss both intra- and postoperatively. Hematocrits of 21 to 25% should increase consideration for blood transfusion. Packed red blood cells (10 mL/kg) will increase the hematocrit by 10%. Initially, lost blood should be replaced with 3 mL of normal saline for each 1 mL of blood lost or with a volume of colloid solution, such as 5% albumin, equal to the volume of blood lost. Depending on the extent and length of the surgical procedure and the exposure of vascular beds, additional fluid administration at 3 to 10 mL/kg per hour may be necessary. Because gluconeogenesis in neonates is underdeveloped, it may be necessary to add some glucose to the maintenance IV fluids for those who were receiving glucose infusions in the preoperative period. However, surgery elicits a stress response, and children are generally able to maintain normal serum glucose levels without exogenous glucose administration.²⁷ In any case, hyperglycemia is always best avoided because it may exacerbate neurologic injury if ischemia occurs.

Brain swelling can be initially managed with hyperventilation and elevation of the head above the heart. Should these maneuvers fail, mannitol can be given IV at a dose of 0.25 to 1.0 g/kg. This will transiently alter the cerebral hemodynamics and raise the serum osmolality by 10 to 20 mOsm/kg.²⁸ However, repeated dosing can lead to extreme hyperosmolality, renal failure, and brain edema.²⁹ Furosemide is a useful adjunct to mannitol in decreasing acute cerebral edema and has been shown in vitro to prevent rebound swelling due to mannitol.^{29,30} All diuretics will interfere with the ability to use the urine output as a guide to the intravascular volume status.

82.3.7 Monitoring

Patients undergoing major craniotomies and spine surgery are at risk for sudden hemodynamic instability due to hemorrhage, VAE, herniation syndromes, and/or manipulation of the

cranial nerves. The potential for cerebral hypoperfusion generally warrants placement of an arterial cannula for continuous blood pressure monitoring and access for sampling serial blood gases, electrolytes, glucose levels, and hematocrit. Although it may initially appear counterintuitive, small patient size decreases the threshold for inserting an arterial catheter because small children cannot tolerate as much blood loss as adults can.

The utility of central venous catheterization remains controversial. In adults, cannulation of the jugular or subclavian veins with catheters that have multiple orifices is often preferred, particularly when VAE are anticipated. However, these catheters are too large for infants and most small children. Furthermore, the central venous pressure may not accurately reflect intravascular volume in small children, particularly when they are in the prone position. Therefore, the risks of a central venous catheter may outweigh the benefits. In infants, even when VAE occur, the use of a central venous catheter for aspirating air is not frequently successful, presumably because of the high resistance of the small-gauge catheters placed in these patients.³¹

VAE have been detected during many craniotomies in infants and children, primarily because the head of a small child is large in relation to the rest of body and rests above the heart when the child is in either the prone or supine position (► Fig. 82.7).^{32,33} Standard neurosurgical techniques may elevate the patient's head even further by raising the head of the table to improve cerebral venous drainage. This maneuver can increase the risk for air entrainment into the venous system through open venous channels in bone and sinuses.¹⁴ Patients with cardiac defects and the potential for right-to-left shunting, such as those with a patent foramen ovale or patent ductus arteriosus, are at risk for paradoxical air emboli leading to potential cerebral or myocardial infarction. A precordial Doppler ultrasound device can detect minute VAE and should be routinely used in conjunction with an end-tidal carbon dioxide analyzer and arterial catheter in all craniotomies to detect VAE early, before significant hemodynamic instability develops. The Doppler probe is best positioned on the anterior chest, usually just over or to the right of the sternum at the fourth intercostal space (i.e., the nipple line). An alternate site on the posterior thorax can be used in infants weighing approximately 6 kg or less who are in the prone position.³⁴ In addition to the characteristic changes in Doppler sounds, sudden decreases in end-tidal CO₂, dysrhythmias, and/or ischemic changes in the electrocardiogram can occur with VAE.

Table 82.7 Rate of maintenance of fluid administration

Weight (kg)	Rate
≤ 10	4 mL/kg/h
10–20	40 mL + 2 mL/kg/h for every kg > 10 kg
≥ 20	60 mL + 1 mL/kg/h for every kg > 20 kg

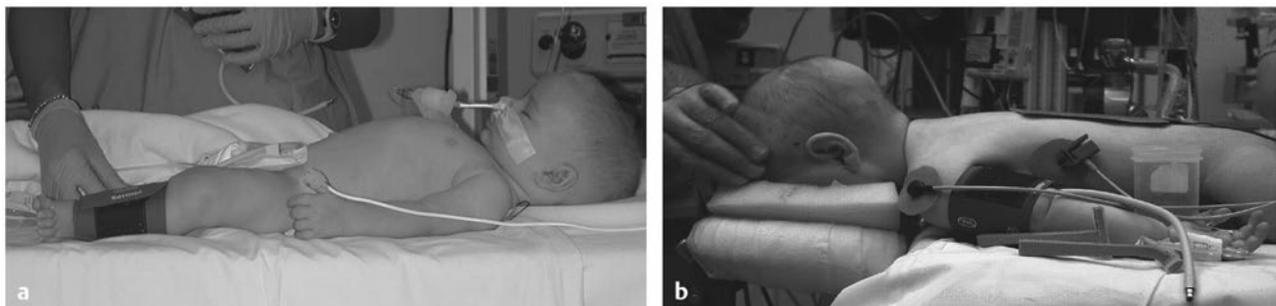

Fig. 82.7 (a) Supine and (b) prone infant. Note that the infant's head lies at a higher plane than the rest of his body. This increases the likelihood for venous air embolism during craniotomies.

Neurophysiologic Monitoring

Recent advances in neurophysiologic monitoring have enhanced the ability to perform more definitive neurosurgical resections safely in functional areas of the brain and spinal cord. However, the depressant effects of many anesthetic agents limit the utility of these monitors. A major part of preoperative planning should include a thorough discussion of the modality and type of neurophysiologic monitoring to be used during any surgical procedure. In general, electrocorticography (ECoG) and electroencephalography (EEG) can be used when levels of volatile anesthetics are low. Somatosensory evoked potentials (SSEPs), used during spinal and brainstem surgery, can also be depressed by high levels of volatile agents and, to a lesser extent, nitrous oxide. An opioid-based anesthetic is the most appropriate agent for this type of monitoring. Spinal cord and peripheral nerve surgery may require electromyography (EMG) and the detection of muscle movement as an end point. Therefore, muscle relaxation should be either avoided or permitted to dissipate during the monitoring period. ▶ Table 82.8 lists common anesthetic agents and their effects on various neurophysiologic monitors.

Monitoring of Cerebral Oxygenation

The primary cause of cerebral ischemia in infants and children is cerebral hypoperfusion secondary to systemic arterial hypotension, especially when it is accompanied by intracranial hypertension. The three potential clinical intraoperative modalities for monitoring cerebral ischemia are (1) EEG, (2) transcranial Doppler, and (3) near-infrared spectroscopy. However, during the routine use of these monitoring modalities, technical difficulties with positioning and recording are frequently encountered because of the proximity of the surgery. Clinical

studies have yet to demonstrate any clinical improvement with their use in the intraoperative setting.

Detection of Seizure Foci

Recent advances in neurophysiologic monitoring have enhanced the ability to perform more definitive neurosurgical resections safely in functional areas of the brain and spinal cord. However, the depressant effects of many anesthetic agents limit the utility of these monitors. A major part of preoperative planning should include a thorough discussion of the modality and type of neurophysiologic monitoring to be used during the surgical procedure. In ECoG, grid and strip electrodes are placed on the surface of the brain following dural opening. Because some epileptogenic foci are in close proximity to cortical areas controlling speech, memory, and motor or sensory function, monitoring of the patient's electrophysiologic responses is frequently used to minimize iatrogenic injury to these areas.^{35–37} The detection of cortical stimulation of the motor strip in a child under general anesthesia will require either EMG or the direct visualization of muscle movement. Neuromuscular blockade should not be used in this situation. Cortical stimulation is possible with a dual-channel stimulator. Epileptogenic activity may be evidenced by clearly documented electrographic seizures or EEG spike activity, which consists of either interictal spikes of 50 to 80 milliseconds or sharp waves of 80 to 200 milliseconds. During anesthesia, the use of low concentrations of volatile anesthetics or nitrous oxide and opioids alone should avoid the attenuation of ECoG and EEG signals.

Monitoring in Awake Craniotomy

Neural function is best assessed in an awake and cooperative patient.³⁸ Positioning of the patient is critical for the success of

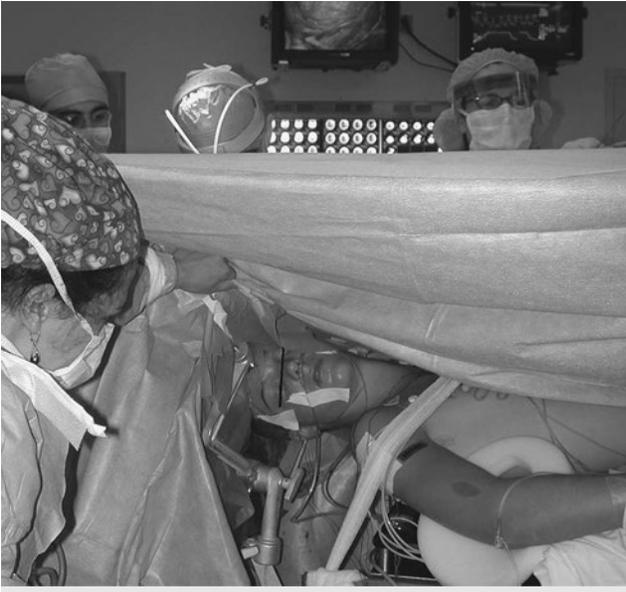

Fig. 82.8 Positioning the patient for an awake craniotomy. Note that there is clear access to the patient to facilitate neuropsychological testing.

this technique. A semilateral position allows both patient comfort and surgical and airway access to the patient (► Fig. 82.8). Motor and sensory regions of the cortex are localized by inducing motor movements or sensory changes with cortical stimulation. Language function is tested by eliciting speech arrest with cortical stimulation. Verbal memory is tested by stimulating the hippocampus or lateral temporal cortex. In a series of children undergoing awake craniotomy, in which local anesthesia and propofol and fentanyl or dexmedetomidine were used for sedation and analgesia during the resection of eloquent areas of the brain, we found that propofol, when discontinued 20 minutes before monitoring, did not interfere with ECoG, and cooperative children older than 10 years were able to withstand the procedure without incident.³⁹ However, it is imperative that candidates for an awake craniotomy be mature and psychologically prepared to participate in this procedure. Therefore, an awake craniotomy should not be considered appropriate for patients who are developmentally delayed or have a history of severe anxiety or psychiatric disorders. Very young patients cannot be expected to cooperate during these procedures and usually require general anesthesia with extensive neurophysiologic monitoring to minimize inadvertent resection of the eloquent cortex.

Monitoring Spinal Cord and Nerve Root Integrity

Surgery on the central neural axis exposes the patient to spinal cord injury or ischemia and nerve root damage. The instrumentation and surgical resection of spinal cord lesions risk damage to the spinal cord and nerve roots not only by direct injury but also by compromise of the arterial supply of the cord. Furthermore, brainstem surgery places vital nuclei and spinal pathways at risk for ischemia and direct damage. Monitoring SSEPs and performing an intraoperative wake-up test help detect these possible complications during surgery. Assessing motor evoked potentials (MEPs) may be helpful as well.

Somatosensory Evoked Potentials

SSEPs monitor primarily the integrity of the dorsal (sensory) pathways of the spinal cord.⁴⁰ This modality provides real-time examination of the spinal tracts at risk during surgical manipulation of the spinal cord. A peripheral stimulus is applied to a distal nerve (the posterior tibial or median nerve). The cephalad progression of the stimulus can be detected along the popliteal fossa, lumbar spine, cervical spine, and cerebral cortex. Stimuli originating from the median nerve generate a detectable signal at Erb's point. The use of anesthetic drugs, in particular high concentrations of volatile inhalation agents, during spinal cord and brainstem surgery can depress SSEP signals. Incremental IV doses or the continuous infusion of a short-acting opioid, such as fentanyl, supplemented with nitrous oxide and/or low-dose isoflurane, may be preferable. SSEP monitoring in pediatric patients appears to be more sensitive to the depressant effects of general anesthesia.⁴¹ Cortical responses were less reliable in children younger than 10 years old and in those with myelodysplasia or cerebral palsy. Although the SSEPs obtained from these patients demonstrated attenuated cortical responses, relatively robust signals were recorded from the cervical spine. The authors recommended that levels of isoflurane and nitrous oxide be maintained below 0.6% and 50%, respectively.

Motor Evoked Potentials

The major drawback of SEP monitoring is that it cannot reliably monitor the integrity of the ventral (motor) pathways. The assessment of motor function is limited by the depressant effect of general anesthetics. In MEP monitoring, magnetic stimulation of the motor cortex with detection of the action potential in the corresponding muscle groups is used to assess motor function. All volatile anesthetic agents, including nitrous oxide, have a dose-dependent depressant effect on MEPs. MEPs appear to be preserved during propofol or dexmedetomidine infusions.^{42,43} However, a dose-dependent attenuation of MEPs appears to occur, and the optimal dosing regimens need to be determined.

Nerve Root Monitoring

Neurosurgical procedures for tethered spinal cord syndrome and spasticity often employ EMG monitoring during identification and dissection of the nerve roots. The tethered spinal cord syndrome resulting from spinal dysraphism is associated with conditions like myelomeningocele, lipoma of the filum terminale, spina bifida occulta, and adhesions from prior spinal surgery. Persistence of this anatomical anomaly can lead to cord or nerve root distortion and impaired perfusion of the spinal cord, with progressive neurologic deficits and chronic pain. The visualization and identification of functional nerve roots may be difficult, so that inadvertent injury can occur during the surgical dissection. This can lead to fecal and urinary incontinence and an exacerbation of lower extremity neurologic dysfunction. EMG monitoring can be helpful for identifying functional nerve roots. Placing EMG electrodes in the external anal and urethral (in girls) sphincters allows continuous monitoring of the nerve roots supplying the pudendal nerves (S2–S4). Inserting a balloon manometer into the bladder and recording changes in pressure during stimulation can assess detrusor muscle

Fig. 82.9 Assessment of motor function during nerve root surgery. Evoked motor responses can be observed through the clear drapes.

function. Movement and evoked action potentials of the anterior tibialis muscle and gastrocnemius and soleus muscles can also be detected visually and by EMG, respectively. Muscle contractions can be readily observed if clear sterile plastic drapes are used (► Fig. 82.9). Muscle relaxation must be discontinued or allowed to dissipate to detect motor activity. Volatile anesthetics and opioids do not appear to interfere with muscle action potentials; the patient should be deeply anesthetized because direct nerve root stimulation often elicits a significant sympathetic response and pain.

Severe spasticity associated with cerebral palsy can be surgically alleviated by a selective dorsal rhizotomy. In this procedure, spasticity is reduced by surgically dividing dorsal rootlets to diminish the afferent input to motor neurons in the spinal cord, thus decreasing the hyperactive reflexes associated with spastic diplegia. Pathologic rootlets are identified by directly stimulating them and noting the corresponding muscle action potential with EMG. Exaggerated action potentials can be elicited in innervated as well as other distal muscle groups. Abnormal rootlets are partially sectioned to decrease afferent nerve conduction. However, the rootlets may contain sensory and proprioceptive fibers.

Another neurophysiologic modality for monitoring spinal cord reflexes is the Hoffmann H-reflex, which is a measure of motor neuron excitability and is significantly increased in children with spastic diplegia. This response can be evoked by directly stimulating the nerve root. The direct efferent muscle response and the Hoffmann reflex are recorded (► Fig. 82.10). The latter represents the reflex potential emanating from the motor neurons of the spinal cord.⁴⁴ Use of the Hoffmann reflex as a guide for measuring the relative degree of spinal reflex hyperactivity during the partial sectioning of pathologic rootlets is more precise. Anesthetic agents limit the utility of the Hoffmann reflex as an intraoperative monitor of spinal reflex activity. Inhalational agents, nitrous oxide, barbiturates, and benzodiazepines all depress the Hoffmann reflex.⁴⁵ The administration of an opioid-based anesthetic with intermittent doses of ketamine or propofol does not appear to suppress the Hoffmann reflex. Because the EMG is the observed end point, muscle relaxation should be avoided

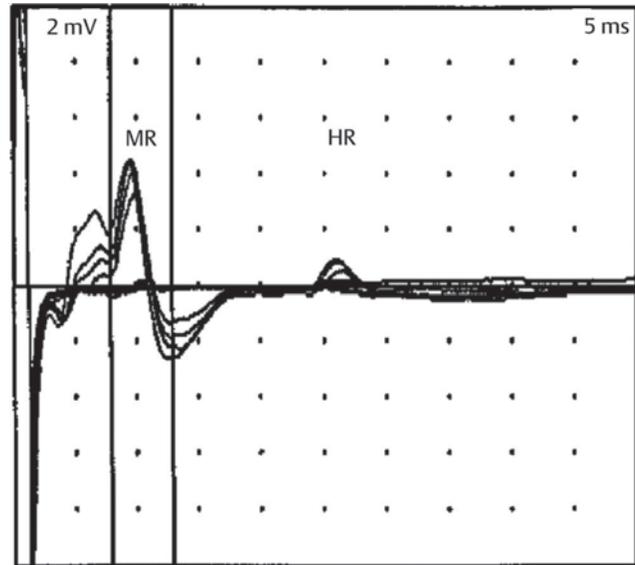

Fig. 82.10 H-reflex. The motor response (MR) occurs at 10 milliseconds, and the H-reflex (HR) follows at 30 milliseconds.

82.4 Postoperative Management

Close observation in an intensive care unit with serial neurologic examinations and invasive hemodynamic monitoring is helpful for the prevention and early detection of postoperative problems. Respiratory dysfunction is the leading complication after posterior fossa craniotomy.⁴⁶ Airway edema is usually self-limited and may require endotracheal intubation as a stent. Occasionally, ischemia or edema of the respiratory centers in the brainstem will interfere with respiratory control and lead to postoperative apnea. Residual narcotics can also produce apnea, but this is transient and can be pharmacologically antagonized with naloxone. Children with Chiari malformations may be more prone to respiratory depression.⁴⁷ Postoperative nausea and vomiting can cause sudden increases in ICP and should be treated with a nonsedating antiemetic. However, the prophylactic administration of ondansetron during surgery has not been effective in decreasing the incidence of vomiting following craniotomies in children.⁴⁸ Although the efficacy of the intraoperative administration of antiemetic drugs as a prophylactic measure is controversial, ondansetron (50 mcg/kg), dexamethasone (0.25 mg/kg), and/or metoclopramide (150 mcg/kg) can be used to treat nausea and vomiting in the postoperative period. Pain control is another issue that complicates the postoperative recovery of patients. Given the sedating effects of analgesic drugs, a delicate balance between pain control and patient responsiveness is essential to allow frequent assessment of the child's neurologic status. One of the most commonly used opioid drugs is morphine. It is administered by the patient's nurse (0.05 to 0.1 mg/kg every 2 to 4 hours) or via patient-controlled infusion pumps in children old enough to cooperate with the technology.

Fluid and electrolyte derangements can occur in the postoperative neurosurgical patient. Serum electrolytes should be measured frequently to detect evolving derangements. Hyponatremia can develop as a consequence of the administration of

hypotonic fluids or the syndrome of inappropriate antidiuretic hormone secretion and can lead to postoperative seizures. Hyponatremia occurs less frequently but should herald the presence of diabetes insipidus or cerebral salt-wasting syndrome. Diabetes insipidus can occur after surgery in the region of the hypothalamus and pituitary gland. The diagnosis can be confirmed by the presence of polyuria (>4 mL/kg per hour), increased serum osmolarity (>300 mOsm/kg), and increased serum sodium (>145 mEq/L). It can be managed acutely with an IV infusion of vasopressin (1 to 5 mU/kg per hour) and the judicious administration of fluid.⁴⁹ Vasopressin has a short half-life and can be titrated to effect (normal urine output, serum osmolality, and sodium concentration). Once the patient is able to tolerate oral intake, vasopressin can be substituted with desmopressin acetate (DDAVP).

Situations may arise in which the patient will require postoperative tracheal intubation and mechanical ventilation. Intraoperative events that most commonly lead to this requirement include neurologic dysfunction and massive blood loss with transfusion. Sedation protocols need to be tailored for the neurosurgical patient to facilitate serial neurologic examinations. Various regimens include midazolam, fentanyl, remifentanyl, and dexmedetomidine infusions. Propofol infusion syndrome has been associated with long-term, high-dose propofol infusion and is characterized by metabolic acidosis, hyperkalemia, rhabdomyolysis, and progressive myocardial failure.⁵⁰ Supportive therapy appears to be the only viable treatment option. Until a controlled prospective analysis of prolonged propofol infusion is performed and the responsible toxin, if one exists, is identified, it is prudent to minimize infusion rates to below 3.0 mg/kg per hour and not to maintain propofol infusions for extensive periods of time.⁵¹

The treatment of postoperative pain is a major component of the perioperative management of the neurosurgical patient. Because most patients who have undergone a craniotomy are observed in a critical care unit, IV opioids (morphine, 0.1 mg/kg IV every 2 to 4 hours as needed) can be carefully titrated to blunt pain, but not to the point of oversedation. Patient-controlled IV opioid infusion pumps can be used by children 7 years old and older; they can also be used by precocious 5-year-olds. Local anesthetics and opioids administered through epidural catheters can provide pain relief for patients who have undergone spine surgery. For patients who are recovering in a less intensive setting, acetaminophen (10 to 15 mg/kg) and codeine (0.5 mg/kg) can be given orally with minimal side effects.

82.5 Special Issues

82.5.1 Neonatal Emergencies

Most neonatal surgery is performed on an emergent basis, which increases risk in the perioperative period.⁵² Congestive heart failure can occur in neonates with large cerebral arteriovenous malformations; this condition requires aggressive hemodynamic support. More commonly, intracardiac right-to-left shunting occurs through a ductus arteriosus or foramen ovale that has not yet closed. Management of the neonatal respiratory system may be difficult because of the diminutive size of the airway, as well as the presence of craniofacial anomalies, laryngotracheal lesions, and acute (hyaline membrane disease,

retained amniotic fluid) or chronic (bronchopulmonary dysplasia) disease. Because these conditions are in a state of flux, they should be addressed preoperatively to minimize perioperative morbidity.

The neonatal CNS is capable of sensing pain and mounting a stress response after a surgical stimulus; therefore, premature infants require anesthesia for painful procedures.⁵³ However, immature neonatal organ systems are highly sensitive to anesthetic agents. Neonatal myocardial function is particularly sensitive to both inhaled and IV anesthetics, and these agents need to be administered judiciously to block the surgical stress response without causing myocardial depression. The administration of an opioid-based anesthetic is generally the most stable hemodynamic technique for neonates. However, the hepatic and renal systems are not fully developed, and neonates anesthetized with a narcotic technique will often have a delayed emergence and may require postoperative mechanical ventilation.

The closure of a myelomeningocele or encephalocele presents special problems. Positioning the patient for tracheal intubation may rupture the membranes covering the spinal cord or brain. Therefore, careful padding of the lesion (► Fig. 82.11) by elevating the neonate on top of soft supports with a hollow center will minimize rupture of the fragile membranes. In some cases, it may be necessary to intubate the trachea with the neonate in the left lateral decubitus position. General anesthesia should be provided to optimize the surgical condition and minimize pain. Most surgical closures of simple myelomeningoceles have relatively minimal blood loss. However, large lesions may require the significant dissection of cutaneous tissue to cover the defect, and these procedures pose greater risks for blood loss and hemodynamic instability. Recent advances in the management of myelomeningoceles have led to early intervention in the intrauterine period.⁵⁴ The management of the fetus and mother during fetal surgery has been reviewed extensively elsewhere.⁵⁵

82.5.2 Craniosynostosis

Remodeling of a craniosynostosis is likely to have the best result if done early in life.⁵⁶ However, these procedures can be

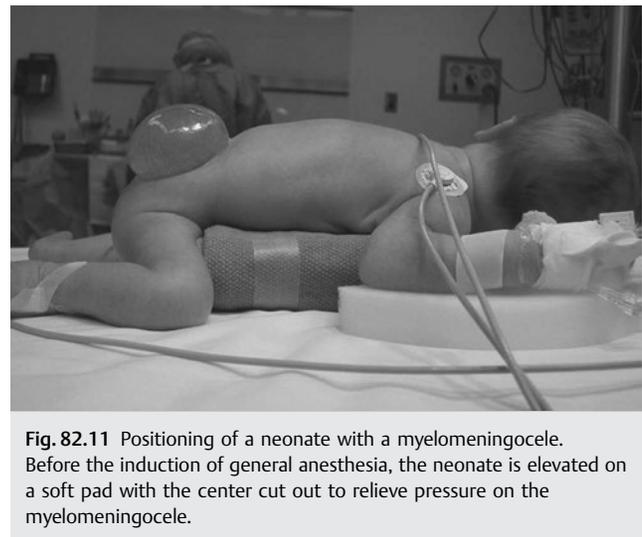

Fig. 82.11 Positioning of a neonate with a myelomeningocele. Before the induction of general anesthesia, the neonate is elevated on a soft pad with the center cut out to relieve pressure on the myelomeningocele.

associated with the loss of a significant percentage of an infant's blood volume, and greater losses occur when more sutures are involved.³³ The use of an antithrombotic drug, such as tranexamic acid, has been shown to reduce blood loss and the need for blood transfusions in pediatric patients undergoing craniotomy surgery.⁵⁷ VAE frequently occur and should be minimized by maintaining adequate intravascular blood volume. Early detection with continuous precordial Doppler ultrasound can make it possible to institute treatment before large amounts of air are entrained. When hemodynamic instability does occur, the operating table can be placed in the Trendelenburg position. This maneuver will augment the patient's blood pressure and prevent the further entrainment of intravascular air. Special risks exist in neonates and young infants because potential right-to-left cardiac mixing lesions can result in the formation of arterial emboli. Minimally invasive techniques in which endoscopy is used for craniotomy repairs have dramatically reduced morbidity in selected patients and reduced the need for invasive anesthetic management.⁵⁸

82.5.3 Tumors

The majority of intracranial tumors in children occur in the posterior fossa; hence, CSF flow is often obstructed and intracranial hypertension and hydrocephalus are often present. Most neurosurgeons approach this region with children in the prone position. The patient's head is generally secured with a Mayfield head frame, although the use of pins in small children can cause skull fractures, dural tears, and intracranial hematomas. Elevation of the bone flap can result in sinus tears, massive blood loss, and/or VAE. The surgical resection of tumors in the posterior fossa can also lead to brainstem and/or cranial nerve damage. ▶ Table 82.9 lists some of the signs of encroachment on these structures. Damage to the respiratory centers and cranial nerves can lead to apnea and airway obstruction after extubation of the patient's trachea. The use of intraoperative magnetic resonance imaging techniques in the pediatric neurosurgical suite presents unique management issues that are justified by the benefits of immediate imaging of the surgical site.⁵⁹ Small children undergoing stereotactically guided radiosurgery require general anesthesia to tolerate the procedure. Special head frames devised to allow airway manipulations should be used in these patients.⁶⁰

82.5.4 Epilepsy

Surgical treatment has become a viable option for many patients with medically intractable epilepsy. Two major considerations should be kept in mind. The long-term administration of

anticonvulsant drugs, such as phenytoin and carbamazepine, induces rapid metabolism and promotes the clearance of several classes of anesthetic agents, including neuromuscular blockers and opioids.⁶¹ Therefore, the anesthetic requirements for these drugs are increased, and close monitoring of their effect and frequent redosing are necessary. Intraoperative neurophysiologic monitors can be used to guide the actual resection of the epileptogenic focus, and general anesthetics can compromise the sensitivity of these devices.⁶² Furthermore, if cortical stimulation is used to mimic the seizure pattern or identify areas on the motor strip, neuromuscular blockade should be antagonized or permitted to abate.

Occasionally, a repeat craniotomy must be performed in a child shortly after the primary procedure. This can be emergent for the evacuation of intracranial hemorrhages. Moreover, an elective repeat craniotomy may be necessary for removal of the ECoG grids and strips used in invasive EEG monitoring and for subsequent resection of the seizure focus. It is important to avoid the administration of nitrous oxide until the dura is opened because intracranial air can persist for up to 3 weeks following a craniotomy, and nitrous oxide in these situations can cause a rapid expansion of air cavities and result in tension pneumocephalus.⁶³

82.5.5 Vascular Anomalies

Vascular anomalies are rare in infants and children. Most are congenital lesions that present early in life. Large arteriovenous malformations in neonates may be associated with high-output congestive heart failure and require vasoactive support. The initial treatment of large arteriovenous malformations often consists of intravascular embolization in the radiology suite.⁶⁴ Operative management is commonly associated with massive blood loss, and patients require several IV access sites and invasive hemodynamic monitoring. Ligation of an arteriovenous malformation can lead to sudden hypertension with hyperemic cerebral edema.⁶⁵ A vasodilator, such as labetalol or nitroprusside, may be necessary to control a hypertensive crisis.

Moyamoya syndrome is a rare, chronic, vaso-occlusive disorder of the internal carotid arteries. It presents as transient ischemic attacks and/or recurrent strokes in childhood. The etiology is unknown, but the syndrome can be associated with prior intracranial radiation, neurofibromatosis, Down syndrome, and a variety of hematologic disorders. The anesthetic management of these patients is directed at optimizing cerebral perfusion.⁶⁶ This includes ensuring generous preoperative hydration and maintaining the blood pressure within the patient's preoperative levels. The maintenance of normocapnia is essential as well because both hyper- and hypocapnia can lead to a

Table 82.9 Effect of surgical manipulation of the brainstem

Brainstem area	Signs	Monitor that is changed
CN V	Hypertension, bradycardia	Arterial pressure, ECG
CN VII	Facial muscle movement	EMG
CN X	Hypotension, bradycardia	Arterial pressure, ECG
Pons, medulla	Arrhythmias, hypo- or hypertension, tachy- or bradycardia, irregular breathing pattern	ECG, arterial pressure, end-tidal carbon dioxide

Abbreviations: CN, cranial nerve; ECG, electrocardiography; EMG, electromyography.

phenomenon of “steal” from the ischemic region and further aggravate cerebral ischemia.⁶⁷ Nitrous oxide and a narcotic-based anesthetic provide a stable level of anesthesia for these patients. EEG monitoring may detect cerebral ischemic events during the intraoperative and postoperative periods.⁶⁸ Once the patient emerges from anesthesia, the same maneuvers that optimize cerebral perfusion should be extended into the postoperative period. These patients should receive IV fluids to maintain adequate cerebral perfusion and should be given adequate narcotics to avoid hyperventilation induced by pain and crying.

82.5.6 Trauma

The management of pediatric head trauma requires a multiple-organ approach to minimize morbidity and mortality.⁶⁹ A small child's head is often the point of impact in injuries, but other organs can also be damaged. Basic life support algorithms should be immediately applied to ensure a patent airway and adequate respiration and circulation. Because the head-to-torso ratio is large in infants and younger children, acceleration-deceleration injuries are more common in the pediatric population and lead to diffuse injuries of the brain and upper cervical spine. Immobilization of the cervical spine is important to avoid secondary spinal cord injury with manipulation of the patient's airway until radiologic clearance is confirmed. Therefore, a patient with an unstable cervical spine should be immobilized with cervical traction during a laryngoscope procedure for tracheal intubation. Blunt abdominal trauma and long-bone fractures frequently occur together with head injury and can be major sources of blood loss. To ensure tissue perfusion during the operative period, the patient's blood volume should be restored with crystalloid solutions and/or blood products. Ongoing blood loss can lead to coagulopathies and should be treated with specific blood components.

Infants with shaken baby syndrome often present with chronic or acute subdural hematomas.⁷⁰ As in all patients who have sustained trauma, coexisting injuries, fractures, and abdominal trauma should be identified. Small children undergoing a craniotomy for the evacuation of an epidural or subdural hematoma are at risk for significant blood loss and VAE. The postoperative treatment of these victims includes the management of intracranial hypertension and, in the most severe cases, a determination of brain death.

The management of pediatric head injury is currently based on a few randomized trials and draws heavily from data derived from adult series; evidence-based management is still evolving. Therefore, a fundamental knowledge of the age-related differences in cerebrovascular physiology and anatomy is essential in the application of adult-based protocols for head trauma in pediatric patients. A multispecialty group of pediatric neurosurgeons and intensivists have published “Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents—Second Edition.”⁷¹ This provides a comprehensive, evidence-based review of controversial management issues in the care of the pediatric patients with head injuries. The goals of therapy should be based on the data obtained from cerebrovascular monitors. Maintaining the cerebral perfusion pressure above 40 mm Hg appears to be associated with the best outcome in pediatric patients. However, studies in infants need to be performed to assess the safety of

even a lower cerebral perfusion pressure. Patients with severe intracranial hypertension, which is refractory to these medical maneuvers, may warrant surgical decompression of hemorrhagic and edematous brain tissue, which may play a role in the management of some infants and children with severe head injuries.⁷² The same principles used for the intraoperative management of patients undergoing craniotomies should be applied in this situation.

82.5.7 Spine Surgery

Spinal dysraphism is the primary indication for laminectomies in pediatric patients. Many of these patients have a history of a meningomyelocele closure followed by several corrective surgeries. They have been exposed to latex products and frequently develop hypersensitivity to latex. Latex allergy can manifest with a severe anaphylactic reaction, heralded by hypotension and wheezing with or without a rash. It should be rapidly treated with removal of the source of the latex and the administration of fluid and vasopressors.⁷³ Patients at risk for latex allergy should be managed in a latex-free environment.

Tethered cord release entails EMG monitoring to help identify functional nerve roots. EMG of the anal sphincter and muscles of the lower extremities is performed intraoperatively to minimize inadvertent injury to the nerves innervating these muscle groups.⁷⁴ Neuromuscular blockade should be discontinued or antagonized to allow accurate EMG monitoring. An epidural catheter inserted by the surgeon under direct vision can provide a conduit for the administration of local anesthetics and opioids for the management of postoperative pain.

82.5.8 Neuroendoscopy

Technological advances in minimally invasive endoscopic surgery have entered the neurosurgical arena. The anesthetic considerations for these evolving techniques are the same as those for any of the other neurosurgical procedures discussed in this chapter.⁷⁵ Because neuroendoscopic techniques are designed to minimize surgical incision, dissection, and blood loss, less aggressive fluid replacement and less invasive hemodynamic monitoring are becoming the norm. Endoscopic strip craniectomy in neonates and infants is associated with decreases in blood loss, surgical time, VAE, and postoperative recovery time.^{58,76–78} Endoscopic third ventriculostomy has become an accepted procedure for the treatment of obstructive hydrocephalus in infants and children.⁸⁰ Despite the relative safety of this procedure, bradycardia, other arrhythmias, and neurogenic pulmonary edema have been reported in conjunction with the use of irrigation fluids (especially when cold) and/or manipulation of the floor of the third ventricle.^{81,82}

82.5.9 Neuroradiology

Recent advances in imaging technology have made it possible to use less invasive procedures to diagnose and treat lesions in the CNS. Most neuroradiologic studies, such as computed tomography and magnetic resonance imaging, can be accomplished with light sedation. Recommendations have been published by consensus groups of anesthesiologists and pediatricians and can serve as guidelines for managing these patients.⁸³

⁸⁴ General anesthesia is typically used for uncooperative patients, patients with coexisting medical problems, and for those undergoing potentially painful procedures, such as intravascular embolization of vascular lesions.⁶⁴

82.6 Summary

The perioperative management of pediatric neurosurgical patients presents an array of challenges to neurosurgeons and anesthesiologists. Many conditions are unique to small children. Thorough preoperative evaluation and open communication between members of the health care team are important. A basic understanding of age-dependent variables and the interaction of anesthetic and surgical procedures is essential in minimizing perioperative morbidity and mortality.

Pearls

- A thorough preoperative organ system–based evaluation of the pediatric patient is essential to minimize perioperative morbidity.
- A larger percentage of the neonate's and infant's cardiac output is diverted to the head. As a result, the patient is exposed to hemodynamic instability during neurosurgical procedures.
- IV and arterial access should be established and secured before the operation because these patients are frequently inaccessible during surgery.
